Although there are exceptions such as sugar beet (Läuchli and Epstein, 1990), most plants are tolerant during germination and can germinate under high salinity conditions including many that are rated as sensitive to salinity such as corn, kenaf, *Limonium*, and tomato (Läuchli and Grattan, 2012). However, salinity stress delays germination even though the final percentage of germinated seeds will eventually be the same among moderate salinity treatments (Maas and Poss, 1989). However, further increases in salinity will eventually reduce the percentage of germinated seeds as well (Kent and Läuchli, 1985).

Unlike germination, many crops are less tolerant to salinity during emergence and as a result stand establishment is reduced (Maas and Grattan, 1999). For example, cotton, a crop classified as 'salt tolerant,' is particularly sensitive to salinity after germination and plant densities have been substantially reduced in fields previously irrigated with saline–sodic drainage water (Grattan *et al.*, 2013). Interestingly, stand establishment of more salt-sensitive crops including safflower and

tomato was not nearly as affected as cotton. Emergence studies have been conducted using different root media under various environmental conditions, making it difficult to interpret results and compare studies. For example, sodic waters, particularly those where NaCl was the sole salinizing salt, can cause deterioration of soil physical conditions thus reducing oxygen diffusion rates and increasing soil strength (Grattan and Oster, 2003). This condition inadvertently adds additional abiotic stresses to the emerging seedlings as compared with other salinity studies under saline and nonsodic conditions.

Vegetative growth

Most of the literature indicates that crops are particularly susceptible to salinity during the seedling and early vegetative growth stage, as compared with germination. Why is the seedling and early vegetative development so susceptible to salinity? It is well known that salinity even with an adequate supply of calcium reduces shoot growth, particularly leaf area, more than root growth (Läuchli and Epstein, 1990). However, inadequate calcium supply under saline conditions (i.e., saline–sodic conditions) can adversely affect membrane function and growth of the root within minutes (Läuchli and Epstein, 1970; Cramer *et al.*, 1988). When the calcium concentration was increased from 0.4 to 10 mmol l^{-1} in a medium salinized with NaCl, root length of cotton seedlings was substantially increased, particularly at the higher salinity levels (Cramer *et al.*, 1986). Moreover, root length at this increased level of Ca^{2+} was maintained over a wide range of salinities. However, shoot growth remained salt sensitive (Kent and Läuchli, 1985). These calcium additions favor cell elongation of cotton roots at the expense of radial cell growth and cell production rates were maintained (Kurth *et al.*, 1986). Additional studies conclude that supplemental Ca^{2+} alleviates the inhibitory effect of salt on cotton root growth by maintaining plasma membrane selectivity of K^+ over Na^+ (Läuchli, 1990, 1999; Zhong and Läuchli, 1994).

The effect of salt stress on shoot growth in many species can also be partly alleviated by supplemental Ca^{2+} (Läuchli and Epstein, 1990; Cramer, 2002), particularly those exposed to high Na/Ca ratios where Ca deficiency in developing leaves may occur (Maas and Grieve, 1987). The calcium status of the growing region of leaves is particularly sensitive to salt stress (Läuchli, 1990). The importance of supplemental Ca^{2+} in alleviating salt stress effects in the shoot has been emphasized by Cramer (2002), and Munns (2002b) recommended adding at least 5–10 mmol l^{-1} Ca^{2+} to the medium for salinities of 100–150 mmol l^{-1} NaCl, to counteract the inhibitory effect of high Na^+ concentrations on growth.

Reduction in shoot growth by salinity is characterized by stunted shoots with reduced leaf area, but the final leaf size depends on both cell division and cell elongation (Läuchli and Epstein, 1990). Although salinity can reduce cell numbers (Munns and Termaat, 1986), leaf extension, controlled by cell elongation, has been found to be an extremely salt-sensitive process (Papp *et al.*, 1983).

Cell expansion is controlled by processes related to cell-wall extension and cellular water uptake (Cramer and Bowman, 1993); the latter depends on the cell osmotic potential (Ψ_s). Hu and Schmidhalter (2004) concluded that the reduction of leaf elongation by salinity may either be related to decreases in cell wall extensibility or increases in yield threshold. In most plants, when leaf elongation partly recovered after the initial rapid drop in the elongation rate upon salinization of the medium, osmotic adjustment occurred with the solute content in the leaf cells becoming higher under saline than nonsaline conditions.

Although leaf expansion is highly responsive to salt stress by reductions in cell elongation, the leaf initiation rate appears less affected. Kriedemann (1986) observed that the rate of leaf expansion in sugar beet decreased linearly with increased salinity whereas the rate of leaf initiation was unaffected.

The relationship between salt sensitivity of leaf growth to the overall salt sensitivity of the plant was hypothesized by Munns and Termaat (1986) using the following model. When NaCl stress is added, the rate of leaf expansion slows down. At the same time, ions begin to accumulate in the leaves in a linear fashion until they reach a maximum concentration beyond which concentrations become lethal and the leaf dies. This first occurs in older leaves, then sequentially in younger leaves as salt stress continues. Eventually, the rate at which leaves die is faster than the rate of leaf expansion, whereby the carbohydrate reserve in the plant is eventually depleted. Leaves no longer expand once the carbohydrate reserves drop to the bare minimum required for further growth. As carbohydrate reserves are depleted yet further, the whole plant eventually dies. The time scale of this process will vary depending on the plant type or genotype and the level of salt stress. The more salt sensitive the plant and more severe the stress, the shorter the time scale. For the plant to survive salt stress, a salt balance in the leaves must be achieved and some minimum fraction of the total leaf area of the plant must remain healthy to continue photosynthesis and carbohydrate production.

The control of sodium acquisition and allocation in plants on the one hand, and carbon allocation and use, on the other, to be critical components of salt tolerance was considered by Cheeseman (1988). A substantial amount of research indicates that photosynthesis per se does not appear to determine plant growth under salt stress for many agronomic crops (Läuchli and Grattan, 2012). Although stomatal conductance is often reduced when plants are exposed to saline conditions, the rates of photosynthesis per leaf area are mostly unaffected (Munns and Tester, 2008) because the chloroplast density per unit leaf area in these salt-stressed plants is higher. However, photosynthesis expressed on a unit of chlorophyll is usually reduced. Overall, photosynthesis measured on a per plant basis is reduced by salinity due to the reduction in total leaf area of the plant (Munns and Tester, 2008). Salt accumulation in the chloroplasts of leaf cells could have a direct toxic effect on photosynthesis, or else salt could reach high enough concentrations in the cytoplasm of leaf cells to inhibit enzymes related to carbohydrate metabolism.

It was suggested among stress physiologists that water deficit in the leaves could limit shoot growth following salinization. Termaat *et al.* (1985) tested this hypothesis to determine whether leaf turgor limits shoot growth in salt-stressed plants by growing plants in a saline soil within a pressure chamber and applying a pressure to the soil media that raised the shoot water potential by the same amount as the pressure applied to the root. Experiments using barley,

wheat, Egyptian clover, white clover, and white lupin indicated that increased leaf water potential did not improve growth under saline conditions (Munns and Termaat, 1986). These results indicate that leaf water deficit does not limit shoot growth in nonhalophytes grown under saline conditions.

The possible role of cell turgor in the response of leaf elongation is unclear. Thiel *et al.* (1988) determined turgor in leaves of salinized barley seedlings by using the micro-pressure probe method and correlated the turgor values with leaf elongation rates. Adding NaCl to the medium caused the leaf elongation rate to immediately decline, followed by gradual recovery, the extent of which depended on the NaCl concentration. Salt stress reduced cellular turgor in expanding and expanded leaf tissue. The turgor of expanding tissue recovered quickly, but decreased turgor persisted in expanded tissue. These researchers suggested that salinity reduced leaf elongation through osmotic effects on turgor in the short term, but the sustained component of reduction in leaf elongation was not caused by leaf water deficit in the long term. The latter part of this conclusion is in agreement with Munns and Termaat (1986). In contrast to the results of Thiel *et al.* (1988), Yeo *et al.* (1991) observed that leaf elongation in rice grown under salinity declined without a change of turgor in the growing zone. Therefore, it appears that the long-term reduction in leaf growth due to salinity is not caused by a leaf water deficit (Munns *et al.*, 2006). Researchers used isopiestic psychrometry on wheat and barley and confirmed that tugor was unchanged when plants were exposed to a range of saline solutions. However, the relative water content (RWC), a widely used method of measuring plant water status, decreased under salinity. Earlier, James *et al.* (2002) and Rivelli *et al.* (2002) showed turgor (calculated from the difference between total water potential and osmotic potential in durum wheat) remained unchanged by salinity whereas RWC decreased. However, RWC, when measured with the conventional method of detaching leaves and rehydrating on deionized water, cannot be used on salt-exposed plants because of osmotic adjustment as a consequence of higher solute content of the cells in a saline medium than in the absence of salinity. The increased cell solute content in the salt-exposed plants leads to a higher uptake of water than in control leaves, resulting in an apparent low RWC in the salinity treatment. Thus, the conventionally used method of determining RWC is not an indicator of turgor in plants that are undergoing osmotic adjustment in response to saline exposure (Läuchli and Grattan, 2012). Additional evidence reviewed recently in detail by Läuchli and Grattan (2007) also indicates no direct role of turgor in the response of leaf elongation to salinity. Indirectly, the evidence supports the conclusion of Munns *et al.* (2006) that hormonal signals are controlling shoot growth and that control of shoot growth under salinity is not mediated by leaf water deficit or ion toxicity.

Reproductive growth

After the salt-sensitive, early-vegetative growth stage, the bulk of the research suggests that most crops become progressively more tolerant as the plants grow older (Läuchli and Grattan, 2007). In experiments with wheat, sorghum, and cowpea conducted at the USDA/ARS Salinity Laboratory (reviewed by Läuchli and Grattan, 2012), when the duration of salinity stress was held constant but the period of salt-stress imposition varied from one developmental stage to the next, investigators found that these crops were most sensitive during vegetative and early reproductive stages, less sensitive during flowering, and least sensitive during the seed filling stage. In all these studies, seed weight was the yield component of interest but similar conclusions regarding growth stage sensitivity were obtained with both determinate crops (the grain crops) and indeterminate (cowpea) crops.

Wheat and rice are not only two of the most important grain crops in the world but they have been the most intensively studied agronomic crops regarding salt sensitivity at different growth stages. These leading grain crops are of particular interest not only because they vary so widely in salt tolerance but also because salinity affects the reproductive processes differently (Läuchli and Grattan, 2007). Studies on wheat and rice were conducted in a variety of conditions including the field, greenhouse, and laboratory to better understand detailed changes in developmental processes, as the plants endure various degrees of salt stress at different growth stages.

Wheat

A mature wheat plant is a consequence of sequential developmental processes that are characterized by changes in shoot apex morphology. The yield components such as tillers per plant, number of spikelets per spike, and individual grain weights are developed sequentially as the crop develops. It has long been known that salinity reduces the growth rate of the entire wheat plant and its specific organs, but it also affects plant development (Hu *et al.*, 2005).

The duration of plant development is also affected by salinity. Salt stress retarded leaf development and tillering but hastened plant maturity (Maas and Poss, 1989). Salt stress, imposed while the shoot apex is in vegetative stage, can adversely affect spike development and decrease yields of wheat (Maas and Grieve, 1990). When wheat was salt-stressed during spike differentiation, reproductive development was stimulated, but the number of spikelets was reduced. Investigators found that salt stress accelerated the development of the shoot apex on the main stem and decreased the number of spikelet primordia. Salt stress decreased the yield potential mostly by reducing the number of spike-bearing tillers. Therefore, Maas and Grieve (1990) concluded that salinity stress needs to be avoided before and during spikelet development on all tiller spikes if full yield potential is to be achieved.

Rice

As one of the most important food crops in the world, both economically and nutritionally, rice ranks among those that are sensitive to salinity (Maas and Grattan, 1999). Not only is rice considerably less tolerant to salinity than wheat but salinity affects its reproductive development quite differently.

Rice sensitivity to salinity varies considerably from one growth stage to the next. In terms of grain yield, rice is tolerant during germination (Heenan *et al.*, 1988), sensitive to salinity during emergence and early seedling growth, becomes more tolerant later on in vegetative development, and then becomes sensitive again during reproductive growth (Flowers and Yeo, 1981; Khatun and Flowers, 1995; Abdullah *et al.*, 2001). The

vegetative shoot biomass of rice, however, is often affected much less than reproductive growth (except for young seedlings) (Khatun and Flowers, 1995; Munns *et al.*, 2002). Field and greenhouse studies have shown that salinity had a negative impact on stand establishment and adversely affected a number of yield components and even delayed heading (Grattan *et al.*, 2002). In one study, investigators found linear decreases in several yield components with increased salinity including the percentage of sterile florets, tillers per plant, and spikelets per panicle, which translated into larger reductions in grain weight per plant at a given salinity (Zeng and Shannon, 2000). However, these investigators suggested that seedling emergence and early seedling growth stages were most sensitive to salinity.

It has long been recognized that salinity can cause sterility in rice, particularly if imposed during pollination and fertilization but some cultivars are more susceptible than others (Akbar and Yabuno, 1977). The effect of salinity on rice has resulted in delayed flowering, a decrease in the number of productive tillers and fertile florets per panicle, and a reduction in individual grain weight (Lutts *et al.*, 1995; Zeng and Shannon, 2000).

The reduction in the number of spike-bearing tillers by salt stress during the vegetative and early reproductive development in most cereal crops appears to have a greater negative impact on grain yield than any other yield component. The time from planting to maturity in most cereal crops typically decreases with increased salinity (Grieve *et al.*, 1993), but salinity has just the opposite effect on rice (Lutts *et al.*, 1995). When salinity was applied to wheat from seedling emergence, it had a profound influence on reproductive development (Grieve *et al.*, 1993). Leaf initiation rate decreased even though the time of flag leaf initiation was unchanged, indicating salinity had no influence on the timing of the transition from vegetative to reproductive development, but greatly reduced the number of tillers and overall grain yield. Salt stress in rice can reduce seedling emergence and, when imposed at early vegetative stages, reduces tillers and grain-bearing panicles leading to low yields. However unlike wheat, certain rice cultivars can develop sterile spikelets, by a mechanism that appears to be genetically controlled, leading to further grain yield losses.

Regulations of Salt Balance in Leaves

Cellular uptake of sodium

Sodium levels in roots increase rapidly after plants have been exposed to salt stress. This is the result of several transport processes, including Na^+ uptake, Na^+ efflux to the apoplast and vacuole, and Na^+ transport to the shoot (Maathuis, 2007). These Na^+ transport processes require the activity of several membrane transporters that are important outputs for signaling pathways. A recent model of signaling pathways for both cellular Na^+ and Ca^{2+} during salt stress illustrates that these transporters may also have sensing functions. Plant roots respond specifically to external Na^+ almost instantaneously, yet the mechanism of Na^+ sensing is still unknown. One proposed hypothesis is that a plasma-membrane protein may function as the extracellular Na^+ sensor (Munns and Tester, 2008). The first response to an increase in salt stress around the roots is an elevated Ca^{2+} activity in the cytosol (Ca^{2+}_{cyt}) of root cells brought about by a flux of Ca^{2+} across the plasma membrane and the tonoplast (Munns and Tester, 2008). The increase in Ca^{2+}_{cyt} in response to salt is a central component of the SOS (salt overly sensitive) pathway. The SOS signaling pathway is composed of SOS1, SOS2, and SOS3 components and has been proposed as a mechanism to mediate cellular signaling under salt stress in order to maintain ion homeostasis at the cellular and whole-plant level (Hongtao *et al.*, 2013). The proposed regulations of these pathways are described in detail in reviews by Hongtao *et al.* (2013), Maathuis (2007), and Qiu *et al.* (2002).

The maintenance of an adequate K^+ concentration in the cytoplasm by favorable K:Na ratios under salt stress is an important feature of salt tolerance in plants. This feature is usually called K^+ homeostasis and is important for maintaining cellular metabolism (Zhu, 2003). A negative correlation between Na^+-induced net K^+ efflux and salinity tolerance in barley plants have been found and it was concluded that the cytosolic K^+/Na^+ ratio is an important determinant of salinity tolerance (Chen *et al.*, 2007), but its significance is probably located mainly in the root, because no strong relationship between leaf K^+ concentrations and salt tolerance has been found so far (Munns and Tester, 2008).

Calcium signaling in response to salt stress

As explained in Section Cellular uptake of sodium, the cytosolic Ca^{2+} activity is involved in the regulation of Na^+ concentration in the cytosol by functioning as a component of Ca^{2+}-signaling network (Hirschi, 2004; **Figure 4**). In the absence of salt stress, the cytosolic Ca^{2+} activity ('resting Ca^{2+}') is low, remaining at approximately 0.1–0.2 μM (Hirschi, 2004). A stimulus such as an increase in external Na^+ concentration elicits Ca^{2+} mobilizing signals. These mobilizing signals trigger a flow of Ca^{2+} into the cytoplasm, which generates the ON events. One of these ON events is the activation of the Na^+/H^+ antiporters at the plasma membrane and tonoplast, which lowers the elevated cytoplasmic Na^+ concentration following exposure to salinity, to low and nontoxic levels. The HIGH Ca^{2+}_{cyt} activates Ca^{2+}-sensitive processes, which are mediated by proteins such as calmodulin. The final step mediated by OFF mechanisms (e.g., transporters and binding proteins) removes Ca^{2+} from the cytosol and restores the Ca^{2+} activity at the resting state. This Ca^{2+}-signaling network is the cellular/subcellular basis for the important role that Ca^{2+} plays in mediating a component of salt tolerance in plants.

Salt exclusion

Regulation of salt balance in the leaves is significant for the salt tolerance of the whole plant. Flowers and Yeo (1986) concluded that for salt-sensitive species, such as rice, sodium supply to the expanding leaves exceeds the demand for osmotic adjustment at high salt stress, leading to excessive sodium concentrations in the leaves and ion toxicity. It is also well established that salt concentrations are highest in the oldest leaves of nonhalophytes (Greenway and Munns, 1980). Yeo and Flowers (1982) suggested that lower salt concentrations in younger leaves may be partly due to exclusion of specific ions

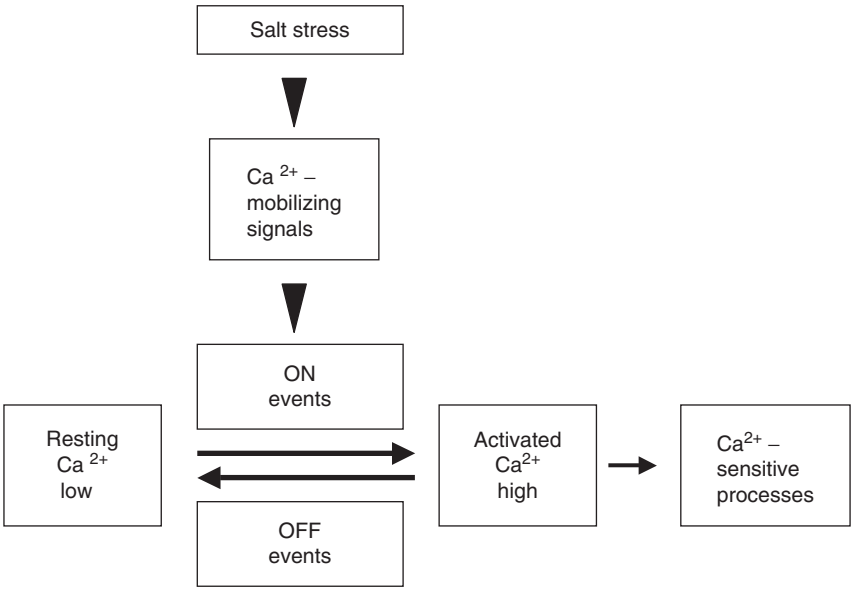

Figure 4 Ca^{2+}-signaling network in response to a stimulus such as salinity stress. Modified from Läuchli, A., Grattan, S.R., 2012. Plant responses to saline and sodic conditions. In: Wallender, W.W., Tanji, K.K. (Eds.), Agricultural Salinity Assessment and Management. ASCE Manuals and Reports on Engineering Practice No. 71, pp. 169–205. New York, NY: American Society of Civil Engineers and Hirschi, K.D., 2004. The calcium conundrum: Both versatile nutrient and specific signal. Plant Physiology 136, 2438–2442, with permission from the ASCE.

from the xylem vessels that supply them. In rice, the evidence clearly indicates that, on salinization, sodium moves first to the older leaves, which in effect protects the younger leaves. This partial exclusion of sodium from the young leaves appears to correlate positively with the salt tolerance of some rice cultivars relative to the germplasm base (Yeo and Flowers, 1986).

As illustrated by Davenport *et al.* (2007), Na^+ accumulation in the shoot is the result of several different transport processes in the root and the shoot (**Figure 5**). Under conditions of high salinity, Na^+ is transported passively into the root cytosol, probably by nonselective cation channels (1). Antiporters such as SOS1 (2) pump Na^+ back from the outer region of the root to the soil solution or sequester Na^+ in the root cell vacuoles by NHX transporters (3). Na^+ can also leak passively from the vacuole to the cytosol (4). The transport processes 1–4 are located in root cortical cells. Transport of Na^+ to the shoot is still poorly understood (Davenport *et al.*, 2007). In the stele of the root, Na^+ is loaded into the xylem, either passively (5) or possibly actively by SOS1 (6). Transport steps 5 and 6 occur in the mature part of the root or at low transpiration. Na^+ retrieval from the xylem, which can take place in the mature region of the root, base of the stem, and along the veins of the leaves, may also occur via the transport processes 5 and 6. Unloading of Na^+ into the leaf cells probably proceeds passively (7). Na^+ can also be recirculated from the leaves to the roots in the phloem (8, 9). The transport steps involved in the net delivery of Na^+ to the xylem have been described in detail by Tester and Davenport (2003). Recently, the thermodynamics of the transport processes and their possible molecular mechanisms have been assessed and summarized by Munns and Tester (2008).

Each of the transport processes that contribute to the net accumulation of Na^+ in the shoot requires their control by specific cell types in specific locations of the plant, thus

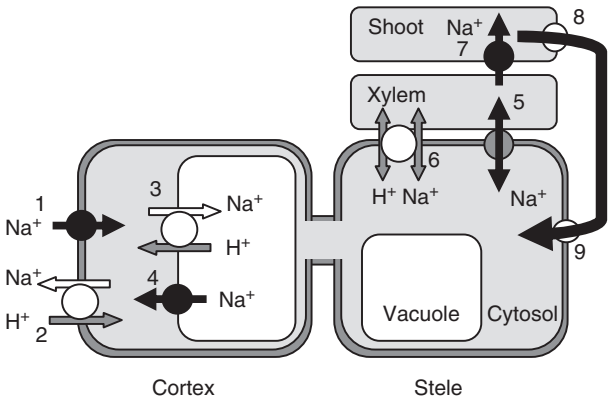

Figure 5 Involvement of different Na^+ transport processes of the root and the shoot in net Na^+ accumulation in the shoot. The numbered processes refer to (1) passive Na^+ transport (nonselective cation channels); (2) SOS1 antiporter; (3) NHX transporter; (4) passive Na^+ transport; (5) passive Na^+ loading in xylem; (6) active Na^+ loading in xylem (SOS1); (7) passive unloading of Na^+; and (8 and 9) recirculation of Na^+ via pholem. Reproduced from Davenport, R.J., Muñoz-Mayor, A., Jha, D., Essah, P.A., Rus, A., Tester, M., 2007. The Na^+ transporter AtHKT1 controls xylem retrieval of Na^+ in Arabidopsis. Plant, Cell and Environment 30, 497–507, with permission from John Wiley and Sons.

facilitating Na^+ transport in a coordinated manner (Tester and Davenport, 2003; Munns and Tester, 2008). A recent experimental example of elucidating the involvement of specific cell types in governing the major control points that limit Na^+ loading of the xylem is given by Läuchli *et al.* (2008) (see also Munns and Tester, 2008). This study indicated that the highest concentration of Na^+ in the cells of a relatively salt-tolerant

durum wheat genotype was found in the pericycle and therefore the pericycle may be the transport control point in the radial transport of Na^+, perhaps limiting xylem loading of Na^+ in the root (Läuchli *et al.*, 2008).

The question arises as to how significant salt exclusion from the shoot is as a mechanism of salt tolerance in non-halophytes. There is a strong correlation between salt exclusion and salt tolerance in many species (see reviews by Läuchli, 1984; Flowers and Yeo, 1986; Munns *et al.*, 2006). In species that retain Na^+ in the woody roots and stems, a strong correlation exists between Cl^- exclusion from the leaves and salt tolerance, especially trees and vines such as citrus, stone fruits, and grapes (Grieve *et al.*, 2012). In durum wheat genotypes, a negative correlation has been found between leaf Na^+ concentration and salt tolerance measured as shoot dry matter production (Munns and James, 2003). In the salt-tolerant wheat genotype, the transport of Na^+ to the leaf blades was maintained at low rates and controlled by xylem loading in the root and sequestration of Na^+ in the leaf sheath. In a recent review, Munns *et al.* (2006) convincingly argued that all plants must exclude most of the Na^+ and Cl^- in the soil solution or the salt concentration in the leaves becomes so high that the leaves are killed. The salt concentration in the soil solution, percentage of salt taken up by the roots, and percentage of water retained in the leaves is given by

$$[NaCl]_{shoot} = [NaCl]_{soil} \times (\%NaCl \text{ taken up}/\%water \text{ retained}) \quad [3]$$

Plants take up approximately 50 times more water from the soil than they retain in the shoot; thus they retain only approximately 2% of the cumulative water absorbed by roots. The vast majority of the water absorbed by roots is transpired by leaves. To prevent the shoot salt concentration exceeding that in the soil, only 2% of the salt should be allowed to move into the shoot; that is, 98% should be excluded (Munns *et al.*, 2006). In fact, most plants exclude approximately 98% of the salt in the soil solution and only 2% is transported in the xylem to the shoots. **Table 2** shows some examples of Na^+ and Cl^- concentrations in the xylem and % Na^+ and Cl^- exclusion from the xylem in plants grown in the presence of 50 mmol l^{-1} NaCl for 2 weeks (see Gregory, 2006; Table 5.9; data from R. Munns, personal communication). The data in **Table 2** show that bread wheat excludes Na^+ more effectively than durum wheat, rice, and barley. Although barley is a relatively poor Na^+ excluder, it is quite salt tolerant because it shows a high degree of 'tissue tolerance' to Na^+. The Cl^- exclusion data in **Table 2** do not correlate with salt tolerance as well as those for Na^+ exclusion, but the relatively salt-tolerant citrus genotype Rangpur lime shows the highest percentage of Cl exclusion. The use of wild relatives to improve salt tolerance of the corresponding crop species has recently been shown to have potential. For example, Teakle *et al.* (2007) compared two Lotus species (perennial forage legumes), *Lotus tenuis* (relatively salt tolerant) and *Lotus corniculatus* (less salt tolerant). *Lotus corniculatus* showed much higher Cl^- concentrations in the xylem and shoot than did *L. tenuis*; thus a higher salt tolerance in *L. tenuis* was correlated with a higher degree of Cl^- exclusion.

Does export of Na^+ and Cl^- from leaves through the phloem effectively help maintain a salt balance in the leaves of a salinized plant? Läuchli (1984) and Flowers and Yeo (1986) concluded that little evidence exists to support this. Munns *et al.* (1986) confirmed this conclusion with an experiment that involved salinized barley. They found phloem export of Na^+ and Cl^- from leaves to be only approximately 10% of the xylem import of those ions. In a more recent study on two genotypes of durum wheat that differ in rates of Na^+ accumulation in the leaves, Na^+ export from the shoot to the root via the phloem was very small (Davenport *et al.*, 2005). Nevertheless, Na^+ recirculation via the phloem may be of some importance in salt tolerance of halophytes (Tester and Davenport, 2003).

Hormonal regulation of salt tolerance

The integration of salt tolerance processes in the plant and their regulation is clearly dependent on the involvement of signaling pathways and plant hormones. This integrated control is a highly specialized field and is beyond the scope of this article. The interested reader is referred to recent reviews such as those prepared by Hasegawa *et al.* (2000), Munns (2002b), Zhu (2002), and Xiong (2007).

Table 2 Salt concentrations in the xylem and % Na and Cl exclusion from the xylem of plants grown in the presence of 50 mmol l^{-1} NaCl for 2 weeks

Species	*Genotype*	*Na^+*		*Cl^-*	
		Xylem exclusion		*Xylem exclusion*	
		Na^+ (mmol l^{-1})	*(%)*	*Cl^- (mmol l^{-1})*	*(%)*
Bread wheat	Janz	0.3	99	3.9	92
	Chinese spring	1.1	98	–	–
Durum wheat	Wollaroi	2.0	96	3.4	93
	Tamaroi	2.7	95	2.7	95
Rice	IR 36	2.8	94	–	–
Barley	Clipper	3.2	94	4.7	91
Citrus	Rangpur lime	2.4	95	1.5	97
	Rough lemon	3.3	93	2.6	95

Crop Response to Saline Field Conditions: Interactive Abiotic and Biotic stresses

Most research that studies the effect of salinity on crops has been conducted in controlled laboratory and greenhouse environments, allowing scientists to better understand detailed responses and determine possible mechanisms the plant uses to cope with this stress. However, such experimental conditions do not reflect the natural conditions the plant encounters in salt-affected areas. There are a number of additional abiotic and biotic stresses that plants often endure under field conditions such as extreme temperatures, water deficits, flooding, nutritional inadequacies, poor physical conditions of soil, pathogens, and pests (Mittler, 2006; Läuchli and Grattan, 2007). Moreover, these stresses are not constant, but vary both spatially and temporally. Therefore, geneticists must be aware that genetically altered plants with higher salt tolerance must also thrive under field conditions with numerous additional interactive stresses for this improved plant to be commercially successful.

In the field, salt-affected crops must also contend with too much or too little water. Therefore, actual crop performance during the growing season is related to how the plant responds to both salinity and fluctuating soil–water conditions, either excessive or deficit.

Flooding

The combined effects of salinity and flooding are common in saline areas, particularly where shallow saline water tables exist or where soils are also sodic, reducing water infiltration and causing water to pond on the soil surface (Barrett-Lennard, 2003). In flooded or poorly drained soils, diffusion of oxygen to roots is reduced, thereby limiting root respiration and plant growth. In addition, important nutrients such as nitrate, sulfate, iron, and manganese can be chemically reduced, decreasing their availability to the plant (Kozlowski, 1997) and selective ion transport processes are disrupted (Drew *et al.*, 1988). Such hypoxic conditions adversely affect crop growth and developmental processes, influence morphological and anatomical adaptations, and cause many physiological dysfunctions in plants. When combined with salinity stress, Na and Cl concentrations increase in the shoot further decreasing plant growth and survival (Barrett-Lennard, 2003).

Water deficit

Plant stress from salinity and water deficit have much in common (Munns, 2002a), but how the plant responds to the combination of stresses remains unresolved (Homaee *et al.*, 2002). Under field conditions, water deficit is practically unavoidable as the soil water content varies temporally and spatially throughout the season. Therefore, some degree of both stresses can be occurring at different times and places in the root zone (Homaee *et al.*, 2002). For example, stress from water deficit may predominate in the upper portion of the root zone whereas salt stress may predominate in the lower portion.

Are the effects of salinity and water stress equivalent? Many evidences suggest that water deficit can be more damaging than an equivalent salt stress (Shani and Dudley, 2001; Shalhevet and Hsiao, 1986). For example, studies have shown that bean, pepper, and cotton were affected more by water stress than by salinity at equivalent reductions in soil water potential (see review by Maas and Grattan, 1999). Although matric and osmotic components are additive from a thermodynamic perspective, there are kinetic factors (i.e., water uptake and transpiration) that must be considered as well (Maas and Grattan, 1999). For example, the rate by which water is supplied to the root by the soil depends on soil water transport properties and evaporative demand. That is, plant response to these stresses under conditions of low evaporative demand is likely to be different than that observed under high evaporative demand as the matric and not the osmotic potential controls water flow to the roots from the surrounding soil. As the soil dries, the matric potential decreases, but increases the resistance of water flow to the roots in a nonlinear fashion (Homaee *et al.*, 2002). However, increases in soil salinity, at a given water content, reduces the osmotic potential but does not reduce water flow to the root. Moreover, the root cortical cells can osmotically adjust to some extent allowing water to readily move into the root. Clearly, the combination of stresses is more damaging than either one alone, but quantifying the growth-limiting contribution of each is difficult and can vary depending on the environmental conditions.

Plant pathogens

Salinity can affect the soil microbe populations in the rhizospere and their interaction with roots. For example, *Rhizobium* spp., which are integral to legume production, seem more salt tolerant than their host plants, but evidence indicates that nodulation and N_2 fixation by some crops are impaired by salinity (Läuchli, 1984). Other investigators have suggested that mycorrhizal symbioses improve the ability of some crops to tolerate salt by improving phosphorus nutrition (see review by Läuchli and Grattan, 2007).

Salt-stressed plants may be predisposed to infection by soil pathogens. Salinity has been reported to increase the incidence of phytophthora root rot in chrysanthemum (MacDonald, 1982) and tomato (Snapp *et al.*, 1991). The combined effects significantly reduced fruit size and yield of tomatoes (Snapp *et al.*, 1991), but wetter soil under salt-stunted plants, due to less evapotranspiration than nonsaline control plants, may contribute to increased susceptibility to fungal diseases. Research on salinity–pathogen interactions is rather limited despite its potential economic impact in salt-affected areas many of which are also prone to waterlogging. Therefore further research is warranted in this area.

Climate

It has long been known that climatic conditions have a profound influence on plant response to salinity. Crops are more sensitive to salinity in hot, dry climates than they are under cooler and more humid environments. The combined effects of salinity and conditions of high evaporative demand, whether caused by high temperature, low humidity, or increased wind are more stressful than salinity stress alone. Numerous crops including alfalfa, bean, beet, carrot, cotton, onion, squash, strawberry, clover, saltgrass, and tomato were found to be more sensitive to salinity at higher temperatures than

they are at lower temperatures whereas at high humidity many crops (e.g., barley, bean, corn, cotton, onion, and radish) were found to be more tolerant to salinity (see review by Läuchli and Grattan, 2007). As climate dramatically affects plant response to salinity, the time of year and location salt-tolerance experiments conducted will likely affect the results.

Soil physical conditions

Poor physical conditions of the soil can also contribute additional stresses in salt-affected areas (Grattan *et al.*, 2013). For example, soils with poor structure or impermeable layers could restrict root growth as well as influence water and salt distribution in the soil. Crusting at the soil surface acts as a physical barrier for emerging seedlings and can lead to poor stand establishment particularly if the young seedlings are already weakened by salt stress. Although there has been a considerable amount of research conducted on salinity and sodicity's effect on soil physical conditions, more research is needed to evaluate how these changes affect crop performance.

Composition of the salts in soil solution

Agricultural soils and irrigation waters around the world vary not only in salinity but also in the composition of salts, which is often characteristic of the geochemical properties of the area (Tanji and Wallender, 2012). In particular, the ratio of sodium to calcium varies dramatically. Gibbs (1970) analyzed the chemical constituents of global waters and found an interesting relationship between salinity and the ratio of Na/(Ca + Na), expressed in mg l^{-1}. Only in very pristine (< 10 mg l^{-1}) or extremely saline (> 10 000 mg l^{-1}) waters were the Na/(Ca + Na) ratio greater than 0.8. The ratio of Na/(Ca + Na) in most water sources used for agricultural production (100–1200 mg l^{-1}) is between 0.05 and 0.6, indicating that calcium is an important salinizing constituent. However, as salts in these waters concentrate due to evapotranspiration and reuse, these ratios increase due to precipitation of calcite and other divalent ion minerals in comparison to sodium (Tanji and Wallender, 2012).

Regardless of the fact that irrigation waters and agricultural soil solutions comprise multiple combinations of cations and anions, the vast majority of salinity experiments on plants use NaCl as the sole salinizing salt. Lazof and Bernstein (1999) discussed the shortcomings of research where not only NaCl was used as the sole salinizing salt but also those studies where nonsaline control treatments contained unrealistic trace amounts of Na and Cl. These investigators emphasize that the trace levels of NaCl in control treatments are problematic in light of observed stimulatory effects from small additions of NaCl up to 5 mmol l^{-1} in many glycophytes. Extremely high Na/Ca ratios, however, lead to nutritional disorders and secondary stresses due to adverse affects on soil conditions.

Not only is NaCl uncharacteristic of agriculturally saline environments, but experiments that use this as the sole salinizing salt create extreme ratios of Na/Ca, Na/K, Ca/Mg, and Cl/NO_3 in the root media (Läuchli and Epstein, 1990). These extreme ratios can adversely affect the mineral-nutrient relationship within the crop than would occur otherwise under normal saline environments (Grattan and Grieve, 1999). Nutrient imbalances in the crop may result from several factors including the effect of salinity on nutrient ion activity and availability, the uptake or distribution of a nutrient within the plant, or increasing the internal plant requirement for a nutrient element resulting from physiological inactivation.

The importance of calcium and its protective role for plants in saline environments has been known for over a century (Kearney and Harter, 1907). Calcium preserves the structural and functional integrity of cell walls and membranes and regulates ion transport and selectivity (Läuchli and Epstein, 1990; Cramer, 2002). Sodium-induced Ca^{2+} deficiency has been observed by numerous investigators when the Na^{+}/Ca^{2+} ratio in the solution, at a given salinity level for a particular plant, increases above a critical level. Crops in the grass family such as barley, corn, rice, sorghum, and wheat are particularly prone to this effect and large differences have been observed among species and cultivars (see review by Läuchli and Grattan, 2007.

Not all salt-affected soils are dominated by chloride salinity (Läuchli and Grattan, 2007). Many salt-affected soils are sulfate dominated such as those found in the Canadian prairie, California's San Joaquin Valley, and parts of Egypt and India. This article found that sulfate was less deleterious to growth than chloride at moderate salinity in alfalfa, pepper, and sorghum whereas at higher salinity levels, sorghum was more sensitive to sulfate salinity than it was to chloride salinity.

Interactions between salinity and boron toxicity

Boron is essential for cell wall structure and plays an important role in membrane processes and metabolic pathways (Brown *et al.*, 2002). However, there is a small range where concentrations in the soil solution are optimal (Gupta *et al.*, 1985). Above this range, boron becomes toxic and below it, boron is deficient. Toxicity can occur in crops when boron concentrations increase in young developing tissue or margins of mature leaves to lethal levels, but plant-tissue analyses can only be used as general guidelines for assessing the risk of B-toxicity (Nable *et al.*, 1997).

It has been known for decades that boron mobility is affected by climatic conditions and that it varies among species (Eaton, 1944). He found that after boron enters the leaf, it remains immobile in most plant species whereas in others, particularly in stone fruits, it can remobilize to fruits and other parts of the plant. More recent evidence has shown that boron can form complexes with polyols in some species allowing it to be phloem mobile (Brown and Shelp, 1997). In other species where these simple sugars exist in small amounts, boron remains immobile. This sheds light on why B-toxicity symptoms occur on margins of older leaves of some plants ('boron immobile') whereas toxicity symptoms appear on younger, developing tissue (i.e., tip dieback) in others ('boron mobile'). In those plants where boron is phloem immobile, boron concentrations in growing tips and reproductive tissue is much lower than concentrations in mature leaves. In boron mobile plants, just the opposite is found.

High boron, like salinity, is an important abiotic stress that adversely affects sensitive crops in many arid and semiarid climates. There are many agricultural areas around the world where both high salinity and high boron occur together (Tanji and Wallender, 2012). The question has recently been raised, are the effects of salinity and boron on crops additive,

synergistic, or antagonistic? From a review of the limited number of studies that addressed the combined effects of salinity and boron on the plant, it appears that the results are contradictory. In some cases salinity may enhance boron sensitivity whereas in others, it may reduce its sensitivity or have no effect. For example, investigators found that salinity enhanced B-sensitivity in wheat (Grieve and Poss, 2000; Wimmer *et al.*, 2001; Wimmer *et al.*, 2003), tomato, and cucumber (Alpaslan and Gunes, 2001) whereas other investigators found that salinity reduced boron's toxic effect in numerous vegetable crops, eucalyptus, and *Prunus* rootstocks (see review by Läuchli and Grattan, 2012). Regardless of these studies, tissue boron concentration was a poor indicator of toxicity. Therefore, it is unclear why crops vary in response to these combined stresses, but salinity can affect the boron distribution in plants and can affect the B-soluble fractions within the shoot (Wimmer *et al.*, 2001; Wimmer *et al.*, 2003). These investigators suggest that the soluble-B fraction in cells is an indicator of B-toxicity in wheat.

Moreover, recent research has shown the pH can have a profound influence on salinity–B interactions (see review by Läuchli and Grattan, 2012). In a controlled sand tank experiment at the USDA/ARS Salinity Laboratory with cucumber, increased salinity, boron, and pH (from 6 to 8) decreased the fruit yield but investigators did not find any significant salinity–boron interaction. However in slightly acidic conditions, regardless of salinity, increased boron was more detrimental than it was in slightly basic conditions. When the experiment was repeated with broccoli, investigators found different results (Smith *et al.*, 2013). They found that an increase in soil–water boron from 1 to 21 mg l^{-1} at pH 6 did not significantly reduce the head yields of broccoli at any salinity level. However at pH 8, as boron increased from 1 to 21 mg l^{-1}, head yields at both low (EC 2 dS m^{-1}) and high (EC 14 dS m^{-1}) were reduced by more than 85%. Interestingly at moderate salinities (EC 5–11 dS m^{-1}), increased boron had very little detrimental effect.

Much has been learned over the past decade regarding salinity–boron interactions but many questions remain unresolved. More research is needed to (1) understand the relationship between visual injury symptoms, tissue boron concentrations, soluble boron fractions, the role pH plays, and how these all interact affecting crop yield and (2) the influence of salinity on the soluble fractions of boron, boron mobility, and distribution within the plant and how these relate to visual injury.

In summary, plants under field conditions often endure multiple stresses during their development. However, the vast majority of research has focused on individual stresses in the absence of others. Plant response to combined stresses cannot be readily extrapolated based on their response to individual stresses (Mittler, 2006).

The potential interactions among several agricultural stress combinations are illustrated in **Figure 6** (Läuchli and Grattan,

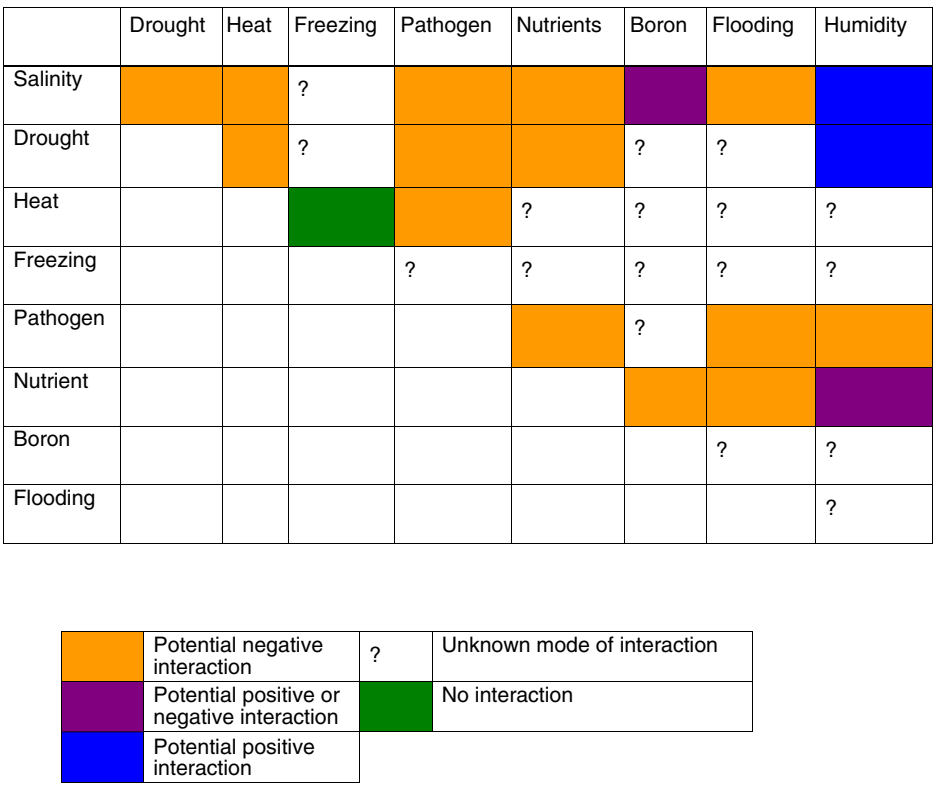

Figure 6 Agriculturally important environmental factors and their potential interactions. Reproduced from Läuchli, A., Grattan, S.R., 2007. Plant growth and development under salinity stress. In: Jenks, M.A., Hasegawa, P.A., Jain, S.M. (Eds.), Advances in Molecular-Breeding Towards Salinity and Drought Tolerance. New York, NY: Springer-Verlag, pp. 1–31 and Mittler, R., 2006. 2007). Some stress combinations show negative interactions whereas others exhibit positive interactions. For some stress combinations, there are no or unknown mode of interactions. Therefore, Mittler (2006) suggested that tolerance to a combination of stresses should be the focus of future research, particularly those where the goal is to develop transgenic crops with enhanced tolerance to natural adverse field conditions. Only by considering these additional stresses that plants endure under field conditions can true advancements be made in salinity tolerance research.

Glossary

Anther dehiscence Splitting of anther pores (apical and basal) to allow pollen shedding on stigma during anthesis.
Anthesis Spikelets open with external protrusion of anthers.
Critical threshold The physiological limit beyond which there is significant loss in plant fitness.
Microsporogenesis The formation of microspores (male gametes) inside the microsporangia (or pollen sacs) of seed plants.
Ontogenetic development Origin and development of an organism from embryo to adult stage.

Introduction

World population is expected to reach 9.2 billion until 2050 (FAO, 2009). To feed this steadily growing population, it is estimated that world food production has to be increased by 70%, with demand for staple cereals, including rice, to increase by 43%. On the contrary, the annual yield increase has steadily declined from 3.2% per annum in 1960 to 1.5% in 2000 as a result of limited genetic biodiversity and changing climate (Powell *et al.*, 2012). Further, global climate models predict with >90% probability that increasing levels of CO_2 and other greenhouse gases may raise global mean air temperature by approximately 1.4–4.5 °C by 2100 (IPCC, 2007). With the increase in daily mean temperature, it is observed that the minimum nighttime temperature is increasing at a faster rate than daily maximum temperature both globally (Vose *et al.*, 2005) and regionally (Peng *et al.*, 2004).

The growth and productivity of rice could be negatively affected by temperature extremes depending on the developmental stage of the crop, and the intensity and duration of stress exposure. Most of the tropical and subtropical rice-growing areas are already close to the documented day temperature threshold of 33 °C (Nakagawa *et al.*, 2002, Teixeira *et al.*, 2011). Any further increase in temperatures coinciding with the sensitive stages such as anthesis and microsporogenesis will reduce spikelet fertility and grain yield (Shah *et al.*, 2011). Furthermore, high temperature affects grain-filling processes by reducing the substrate supply time, substrate translocation, and deposition in the grains (Fitzgerald and Resurreccion, 2009). However, mean seasonal night temperature above 23 °C recorded a 10% decline in yield and biomass for each 1 °C rise (Peng *et al.*, 2004). Likewise, a decline in yield across south and southeast Asian rice-producing regions was recently documented with average monthly night temperatures exceeding 24 °C (Welch *et al.*, 2010).

On the other extreme, cold-temperature stress adversely affects rice at the seedling stage in the subtropics (Ranawake and Nakamura, 2011) and at all growth stages in the temperate regions where it is grown as a summer crop. The critical threshold below which rice plants start to show a negative response is documented to be ≤15 °C (Zhang *et al.*, 2005). In some subtropical regions such as Brazil (comprising approximately 1 million ha of rice), cold stress at the vegetative stage accounts for up to a 20% yield loss (Cruz *et al.*, 2010).

Plants often have a strong adaptive mechanism to cope with unfavorable changes in the environment. However, tolerance of an abiotic stress such as temperature stress is a complex quantitative trait and considerable genetic variability is recorded among genotypes under different environments or within a similar environment. In this article, the authors have summarized the response of rice to extreme temperatures (heat and cold) and the basic mechanisms for adaptation, i.e., avoidance, escape and tolerance, particularly during the sensitive flowering and grain-filling stages. Using rice as a case study, the authors have shown the systematic approaches followed at the International Rice Research Institute, Philippines (IRRI), in an attempt to adapt rice to extreme heat stress and the extended impact of temperature interactions with other environmental factors. The word 'extreme' in this article is used in the context of temperatures above (heat stress) and below (cold stress) the critical thresholds identified for rice.

Response of Rice to Temperature Stress

Vegetative Growth

For most cereals, including rice, the vegetative stage is generally considered to be more tolerant of temperature extremes than other stages. However, tolerance of either cold or heat stress at the vegetative stage does not automatically translate into tolerance at the reproductive stage (Ranawake and Nakamura, 2011). High day temperatures during the seedling stage lead to poor establishment, reduced height, and reduced tillering potential (Shah *et al.*, 2011). Kanno *et al.* (2009) reported that high night temperature under controlled environments promoted vegetative growth and biomass in rice, whereas contrasting results were obtained with a 10% decline in biomass under field conditions (Peng *et al.*, 2004), indicating a knowledge gap with rice response to high night temperature. Conversely, for rice grown in early spring in temperate or subtropical environments, low-temperature effects on seedlings

 doi:10.1016/B978-0-444-52512-3.00172-8

can be manifested as poor germination, slow growth, leaf discoloration or yellowing, withering, reduced tillering, and stunted growth (Andaya and Mackill, 2003).

Reproductive Development

The reproductive phase of the rice crop is known to be highly sensitive to exposure to both temperature extremes (Zinn *et al.*, 2010). High tissue temperature ≥33.7 °C (ambient air temperature of 35 °C) for even less than 1 h coinciding with anthesis is sufficient to induce sterility in rice (Jagadish *et al.*, 2007). The reproductive stage of rice encompasses several processes that are equally sensitive to high temperatures, namely, (1) microsporogenesis and early microspore development, (2) dehiscence of the anther, (3) shedding of pollen, (4) germination of pollen grains on stigma, and (5) pollen tube growth and fertilization (Rang *et al.*, 2011; Jagadish *et al.*, 2012). In the same way for high temperature, the young microspore stage of male gametophyte development is reported to be sensitive for cold stress in rice, resulting in pollen sterility and large yield reductions, a phenomenon that is characteristic of temperate rice-growing regions (Oliver *et al.*, 2007). Pollen sterility triggered by cold stress causes repression of the apoplastic sugar transport pathway in the tapetum, resulting in a disruption of sugar transport in anthers (Oliver *et al.*, 2007). Additionally, high night temperatures negatively affect pollen germination, which subsequently reduces spikelet fertility (Mohammad and Tarpley, 2009). Response of the female reproductive organ to adverse temperature stress is less understood.

Grain Filling and Development

The early phase of grain filling in rice is sensitive to extreme heat, and cumulative heat stress from the reproductive stage to grain filling drastically reduces grain endosperm size, the rate of development, grain number, and grain size (Morita *et al.*, 2005).

At the process level, exposure to high temperature during the grain-filling stage is associated with down-regulation of starch-synthesizing genes, whereas the level of starch-consuming enzymes and heat shock proteins gets up-regulated, ultimately resulting in reduced grain weight (Yamakawa *et al.*, 2007; Yamakawa and Hakata, 2010). Increased temperatures (both daytime and nighttime) accelerate ontogenetic development, so that maturity is reached earlier and the grain-filling duration is shortened. This reduces the time span for translocation of stored assimilates from the vegetative tissue, i.e., stem and leaf sheath, to the grains, leading to increased partially filled grains. Extremely high night temperature may result in increased respiratory losses and cause an insufficient supply of photosynthates to the grain. Similarly, cold stress can potentially reduce the grain development and filling by increased spikelet sterility and reducing photosynthesis and carbohydrate supply. However, information on the direct effect of cold temperature on sink strength and endosperm development in rice is still limited.

Grain Quality

Rice grain quality is characterized by traits grouped under physical appearance and cooking, sensory and nutritive properties (Fitzgerald *et al.*, 2009); of these, grain appearance and eating quality are the major factors that influence cultivar selection by farmers. High temperature greatly increases chalkiness in rice, and reduces gel consistency and amylose content, etc. Among these factors, chalk content is the principal determinant of market revenue. Temperature stress during the early grain-filling stage results in an increase in white core chalk, which determines the proportion of broken (<3/4 the size of a whole kernel) and the head rice (≥3/4 the size of the whole kernel) recovery, and, the greater the broken, the lower the market price (Counce *et al.*, 2005). High temperatures during the later grain-filling period result in white belly (peripheral part of the endosperm) chalk, which does not contribute toward grain breakage but decreases the quality of the visual appearance and hence entails a penalty in the market price. At the same time, some varieties have high assimilate translocation efficiency to compensate for the reduced grain-filling duration in response to increased temperatures, so they can potentially overcome or reduce chalk formation (Kobata and Uemuki, 2004). Furthermore, a rise in mean temperature (~31 °C) can result in a sharp decline in amylose content, resulting in changes in starch composition, which in turn increases the stickiness in cooked rice and reduces the degree of aroma (Nagarajan *et al.*, 2010). Effect of cold stress on rice quality traits is, however, poorly understood.

Temperature Stress Adaptation Mechanisms

Plants have adapted to a range of survival mechanisms under adverse environmental conditions. Rice in response to extreme heat stress exposure during the day can use its avoidance, escape, or true tolerance strategy and ensure normal reproductive success and grain yield.

Heat Avoidance

Changing leaf orientation, transpiration cooling, a reduction in nonphotosynthetic energy intercepted by the canopy and reflection of solar radiation are some ways by which crops avoid heat stress, of which transpiration cooling is perceived to be a dominant mechanism. High day temperatures in association with low humidity allow efficient use of transpiration cooling as long as the water supply is sufficient. High transpiration rates on rice plants are decisive features in hot environments such as in Pakistan, Iran, and Senegal as well as in the highly productive rice-growing regions of Punjab in India with temperatures of ≥38 to 40 °C during the heat-sensitive stages. The low moisture content in the air stimulates plant transpiration, thereby cooling the plant's immediate micro climate by up to 8 °C or more (Wassmann *et al.*, 2009). In the long run, however, with greater pressure on freshwater availability and erratic precipitation patterns, these productive regions are under intense risk with future warming climates. Moreover, the trend toward newer technologies to grow rice under less water, i.e., dry-seeded rice and aerobic rice, may further deteriorate yield potentials in high-temperature regions as these technologies are inherently more sensitive to increasing temperatures.

Heat Escape

As heat stress leads to immediate yield losses, farmers have intuitively adjusted cropping calendars to avoid high temperatures at the sensitive flowering stage. However, the time windows for sowing/transplanting are often restricted by other factors such as seasonal availability of rainfall and optimum radiation patterns to achieve high yields. In turn, adaptation at a micro level, i.e., the time of day of flowering, can be seen as a more promising option given that some rice types are observed to flower even at night. Wild rice (*Oryza officinalis*) flowers in the early morning at 06.00, a trait that will allow the sensitive flowering period to escape the high temperatures during late morning and early afternoon (Sheehy *et al.*, 2007). Recently, the genetic source of variation has been exploited and the chromosomal fragment inducing this change has been identified and introgressed into cultivated japonica and indica entries. This introgression has altered peak flowering to occur up to 2 h earlier in cultivated varieties such as Koshihikari (Ishimaru *et al.*, 2010). Because the actual physiological processes during anthesis, including pollination and pollen germination, are completed during the cooler hours of the morning and with high temperatures having no significant impact on fertility immediately after flowering (Yoshida *et al.*, 1981), early-morning rice accessions maintain good seed-set. This strategy can provide some respite for the immediate concern of extreme heat-induced spikelet sterility but the effect on different developmental stages, particularly microsporogenesis or grain filling, cannot be addressed through this approach and hence would require true heat tolerance or a combination of strategies.

True Heat Tolerance

Heat avoidance is useful in specific regions of high water availability and low relative humidity. However, heat escape depends on the stability of the trait in interaction with other environmental conditions, so that 'true' heat tolerance remains as the more sturdy solution across a wide range of vulnerable rice-growing regions. Incorporating heat tolerance in widely adapted rice varieties would allow reducing heat-induced losses not just at the flowering stage but also at microsporogenesis and other key developmental stages. This approach would require identifying rice entries with the ability to tolerate a higher degree of heat stress (irrespective of their yield or agronomic characteristics), which would translate into normal microsporogenesis and maintain pollen viability, thus allowing fertilization and seed-set to progress. A rice cultivar N22 was consistently identified as the most heat-tolerant accession in response to high day temperatures, and it was also reconfirmed at IRRI as the best performing entry dealing with microsporogenesis and under high night temperature. Although it has poor agronomic traits and low yield potential, its heat tolerance trait is being used in breeding programs at IRRI. Genetic progress at IRRI has resulted in the identification and reconfirmation of the most heat-tolerant accessions of N22, and the chromosomal regions (QTLs) inducing this heat tolerance have been identified (Ye *et al.*, 2012). Additionally, using molecular approaches, three candidate heat shock proteins, possibly having an active role in pollen viability and pollen germination under heat stress, have been identified (Jagadish *et al.*, 2010, 2011) and are being functionally validated through a transgenic approach. This genetic and molecular progress in combination with molecular marker technology will allow transferring heat tolerance into rice mega-varieties.

Acquired tolerance/acclimation involves modification of the crop's structure and function in response to mild stress such that the impact of severe stress is reduced compared to the crop's response in the absence of this modification. After a short exposure to stress or heat shock (<2 h), the plants respond with a cascade of signaling. This cascade starts with key signaling molecules (e.g., calcium, salicylic acid, hydrogen peroxide, etc.) and ultimately results in enhancing antioxidant defense machinery and up-regulating heat shock proteins that induce acquired thermo tolerance (Sung *et al.*, 2003). This temporal expression of defense genes acclimatizes the plant for a definite period and provides tolerance at the susceptible stage exposed to damaging levels of stress.

Cold Escape and Tolerance

Cold temperature ($\leq$10 °C) can seriously hamper seed germination or seedling establishment in rice and likewise low night temperatures are more damaging at reproductive development. Some management practices such as deep standing water at the panicle initiation stage, low nitrogen supply (to expose minimum biomass to cold nights), and adjusting sowing time (early sowing) are being adopted for cold escape. The adoption of new cultivars with traits such as more spikelets per panicle and more panicles and tillers with erect plant type even under low soil nitrogen seems to be effective to minimize yield loss in temperate regions (Anzoua *et al.*, 2010).

At low temperature, the tolerance mechanism employed to ensure survival includes the generation of reactive oxygen scavengers to minimize the effect of increased production of reactive oxygen species, and the accumulation of sucrose and other simple sugars in the apoplastic space to prevent intercellular ice from forming adhesions with cell walls and membranes that cause the cell to rupture (Sanghera *et al.*, 2011). Screening diverse germplasm for cold tolerance traits (e.g., coleoptile length, coleoptile regrowth, spikelet fertility, etc.) and using it in breeding programs can be deemed a promising approach to sustain rice production in temperate regions. Apart from conventional breeding methods, cold acclimation and incorporation of cold tolerance genes through gene pyramiding provide a new avenue for rice production, especially under extreme environments. Rice transgenics with genes such as *OSISAP1* (Mukhopadhyay *et al.*, 2004), *OsMYB3R-2* (Ma *et al.*, 2009), and many others for membrane stability (FAD1-7) and cryoprotectants are reported to be tolerant for cold and other abiotic stresses.

Adapting Rice to High-Temperature Stress – Prospects and Constraints

Adjusting agronomic practices to improve the outcome of crop response to extreme temperature involves many players and

differs from place to place, which makes adaptation an uneasy venture. Adaptation will have to be suited to the local climatic conditions. Some practices followed under high-temperature conditions are growing more tolerant crops, altering planting time to avoid reproductive damage, increasing the use of climate forecasting information to reduce risks and also using resilient agricultural systems (Howden *et al.*, 2007). But, many rice-producing regions (tropical and subtropical) are now at or slightly above the optimum temperature thresholds for rice production, which requires greater interventions under future extreme climatic events.

Some difficulties are associated with adaptation options such as altering planting dates and using short-duration varieties. Although altered planting time is considered and is partly being followed as an option to overcome heat stress, the major concern with extreme heat is the variability of heat spikes more than the rise in mean temperature, which is difficult to predict. Hence, altered planting is a 'hit or miss' option because the heat spikes could occur at any stage of the rice growth cycle. Short-duration rice varieties could be another option in areas with reduced water availability but, in cases where water is sufficient, it is hard to convince farmers to use a shorter duration variety that would invariably have a yield penalty, at times accompanied by undesirable quality parameters. Other problems can also be encountered, for example, delayed rice planting to avoid cold stress during the dry season in the Sahel savanna of west Africa led to serious yield losses mainly due to unexpected early rains. Moreover, long-established cultures and traditions in many rice-producing areas of Asia and Africa do not favor changes in farming practices. Hence, our current research prioritizes the identification of genetic variation for traits such as early-morning flowering or heat tolerance, for example, from landraces and using molecular marker technology to introduce the trait of interest into a farmer-preferred variety. By doing so, farmers still have their preferred variety with no change in yield or grain quality but with the target trait, for example, early-morning flowering or higher temperature tolerance, to overcome heat stress.

Conclusions

To overcome the rapidly increasing temperature effects, efforts have been intensified to identify heat-avoiding rice accessions, incorporating the early-morning flowering from *Oryza officinalis* and the QTLs and genes inducing true heat tolerance into farmer-preferred varieties. Using information from GIS mapping, hot spots for screening early and advanced generation breeding lines have been selected in India and Bangladesh. These hot spots have been grouped into hot-dry (where heat avoidance is an effective trait) and hot-humid (where either early-morning flowering or heat tolerance is more effective). Advances in molecular technology, particularly high-throughput genotyping and molecular marker-assisted backcrossing, are being employed to fast-track the developing rice varieties to withstand rapidly increasing temperatures. Similar approaches to enhance cold tolerance are under way.

Glossary

Gene expression A process by which genes on DNA are transcribed into ribonucleic acid (RNA), which then translates into proteins or functional products.

Gene ontology A major bioinformatics initiative with the aim of standardizing the representation of gene and gene product attributes across species and databases. The project provides a controlled vocabulary of terms for describing gene product characteristics and gene product annotation data from GO Consortium members as well as tools to access and process these data.

Genetic linkage map A map of genes that are located proximally to each other on a chromosome to be inherited together during meiosis.

Microarray A collection of microscopic DNA spots attached to a solid surface. Scientists use DNA microarrays to measure the expression levels of large numbers of genes simultaneously or to genotype multiple regions of a genome.

MicroRNA (miRNA) These are usually not expressed to directly produce proteins, but their presence can affect the expression from other genes that typically do lead to the production of proteins. The small miRNAs sequences target messenger RNAs (mRNAs) to induce cleavage of the mRNAs and repress their translation into proteins.

RNA sequencing A technology that uses the capabilities of next-generation sequencing to reveal a snapshot of RNA presence and quantity from a genome at a given moment in time.

Introduction

Water is the most abundant compound on the earth's surface, covering nearly 70% of the planet. However, only 2.5% of total water on the earth's surface is fresh water (Table 1), i.e., if the earth's total water is equivalent to a gallon then fresh water is 20 teaspoons in volume. Most of the fresh water on the earth is locked up in glaciers as ice and only a small fraction is available in rivers and lakes (Table 1). Owing to the population explosion and economic growth, the majority of fresh water in rivers and lakes is being consumed by urban and industrial users leaving a small fraction for agriculture, with a recent prediction indicating that by 2030, nearly 47% of world population will be living in areas of high water stress (UN-Water). Although excess water can also create stress on plants, these data indicate that fresh water is increasingly becoming a scarce resource on the earth and stress caused by lack of water – commonly referred to as drought stress – is becoming an even more significant factor in limiting food production than it was previously. For the remainder of this article, the authors have referred to the stress of having inadequate water as water stress.

Agriculture depends on rainfall in many regions of the world. Global rainfall pattern is highly variable on a spatial scale and severe droughts have occurred many times in each of the major agricultural regions of the world, including Central United States, Southeastern China, India, Central Europe, Eastern Australia, and Southern Africa, during 1900–93 (Dai *et al.*, 1997). More recently, global drought severity index data captured during 2000–11 indicated that drought has occurred globally at high frequency and intensity (Mu *et al.*, 2013). Notable are the long-term droughts in South and Southeast Asia, Western United States, Central and Southern Africa, and Southern and Eastern Australia (Mu *et al.*, 2013). The duration and intensity of droughts have generally increased globally (Food and Agriculture Organization (FAO) facts). Since 1900, more than 11 million people have died due to drought and more than 2 billion people have been affected by drought (FAO facts). Extensive economic losses (in billion US dollars) have occurred due to drought in the United States, China, Australia, Spain, and other countries (Statista, 2013). The 2011 and 2012 extreme droughts in the United States caused an estimated loss of 20 and 8 billion dollars, respectively (Statista, 2013). Therefore, it is needless to say that water stress has profound effects on the global economy and human society.

Given its importance among abiotic stresses, a modest attempt is made here to summarize several concepts related to water stress in agricultural crops. The purpose of this article is not to provide an in-depth discussion on concepts related to crop water stress. Instead, the article is a summary of concepts that provides enough background to a novice reader while providing an updated review to an experienced reader. The following are discussed in the article: (1) water uptake and loss in crops; (2) water stress effects at the molecular, metabolic, and physiological levels in crops; (3) reducing yield loss under water stress; and (4) industry efforts to develop drought-resistant hybrids/varieties.

Water Uptake and Loss in Crops

Plants experience water stress when water extraction from the roots is less than that lost from the plants (usually from the aerial leaves and stems) determined by the evaporative demand of the atmosphere (Hall, 1993). It is ironic that, in spite of fundamental importance of water on plant metabolism, plant water uptake and loss are controlled largely by the environment and to a lesser extent by the plant. Therefore, to fully appreciate the concept of water stress it is important to understand how water moves from the soil to the plant, inside the plant, and evaporates to the atmosphere from the plant. This path of water movement into, through, and out of a plant

Table 1 Earth water resources

Observation	*Actual*	*%Total water*	*%Fresh water*
Total volume of water	1.4 billion km^3	100	n.a.
Volume of fresh water	35 million km^3	2.5	100
Volume of fresh water in glaciers	24 million km^3	1.7	70
Volume of fresh water stored underground	9.95 million km^3	0.72	27
Volume of fresh water in rivers and lakes	1.05 million km^3	0.08	3
Volume of water in the atmosphere	13 000 km^3	0.000 9	0.04
Volume of fresh water for the ecosystem and humans	200 000 km^3	0.014	0.6

is called the 'soil–plant–atmosphere continuum (SPAC)' and happens due to the gradient in 'water potential' along the path between soil–root, root–stem, stem–leaf, and leaf–atmosphere.

Water potential (denoted as Ψ) is the potential energy per unit volume (or pressure) of water in a system (e.g., soil) relative to that of the pure water at the reference pressure, temperature, and elevation. The water potential of pure water is arbitrarily set at zero; therefore, water potential of any (soil/plant/atmosphere) system is negative. In plant physiology, water potential has units of pressure (Pa for 'pascal') and water moves from a region of high pressure to low pressure. Water potential is influenced mainly by three components viz., gravitational potential (pressure of gravity on the mass of water), pressure potential (physical pressure of water on surfaces), and osmotic potential (pressure due to bonding of water to charged ions, which is related to what is dissolved in the water). The pressure potential is positive when saturated (e.g., water pressure on top of the soil after irrigation or turgor pressure on cell walls) or negative when unsaturated (e.g., matric pressure in the soil or xylem pressure). Gravitational potential is always positive, whereas osmotic potential is always negative.

The major driving force for water movement in the SPAC (pathway from soil through plants to the atmosphere) is the gradient in water potential generated by 'transpiration pull' caused by water evaporating through the process of transpiration from the plant. Water in the plant forms a continuous network of liquid columns from absorbing surfaces of roots to the evaporating surfaces in leaves. Water moves from the regions of high water potential to that of low water potential. The water potential of the atmosphere is very low (at 30 °C and 50% RH, the water potential of the atmosphere is approximately -97 MPa). Because the water potential of the leaf is higher than that of the atmosphere, water evaporates from the leaf to the atmosphere. This lowers the water potential of the adjoining regions of the evaporative surfaces in the leaf and the process continues into the xylem and to the roots, thus establishing a gradient in water potential in the plant that further moves water from the soil into roots to the aerial parts of the plant.

An illustration of gradient in water potential that exists under irrigated or water stress conditions is shown in **Figure 1**. Under irrigated conditions (**Figure 1**), leaf water potential of approximately -1.0 MPa, root water potential of approximately -0.4 MPa, and soil water potential of approximately -0.01 MPa were observed for maize seedlings (Adeoye and Rawlins, 1981). As the soils dried down during water stress (**Figure 1**), soil water potential decreased from approximately -0.01 to -0.6 MPa (moderate drought stress) and root and leaf water potentials further decreased from approximately -0.4 to -1.2 and approximately -1.0 to -1.6 MPa, respectively, in maize seedlings (Adeoye and Rawlins, 1981). Under field conditions, leaf water potentials in the range of -0.5 to -2.5 MPa are commonly seen for crop species (Cary and Wright, 1971). Leaf water potential can change significantly during the day, with maximum values in the morning and minimum values during the afternoon (Cary and Wright, 1971; Acevedo *et al.*, 1979). As the soil dry-down progresses during the drought stress, it becomes increasingly difficult to maintain the water potential gradient and extraction of water from the soil. Generally, a soil water potential of -1.5 MPa is considered the 'permanent wilting point' for crops (Taiz and Zeiger, 2010). At this point, no soil water is available for extraction by roots. Water is held by the soil particles at a pressure equivalent to approximately 15 times greater than the standard atmospheric pressure at permanent wilting point.

Water Stress Effects at the Molecular, Metabolic, and Physiological Level

When plants are exposed to water stress, a large number of molecular, metabolic, and physiological changes occur that, in turn, result in phenotypic changes that enable plants to mitigate the effects of the stress. Stress mitigation is seen as a reduced loss of yield at the field or agronomic scale.

The first step in plant response to water stress is to perceive the stress signal or 'signal perception' (**Figure 2**). The stress signal is perceived by receptors located on the cell surface (e.g., receptors like kinases and ion channel-linked receptors) or stress sensors inside cells (e.g., abscisic acid (ABA) sensor, hexokinases, and reactive oxygen species (Bhargava and Sawant, 2013)). The stress signal perceived by the receptors or sensors is transferred to the nucleus to activate the expression of genes needed to effect change in the plant by a process called 'signal transduction' (**Figure 2**). Some examples of messengers that enable this signal transduction are mitogen-activated protein kinases, calmodulin-binding proteins, and phosphoinositides (Bhargava and Sawant, 2013).

The arrival of stress signals at the cell nucleus results in either up- or downregulation (differential gene expression) of stress-specific genes. Changes in the expression of genes that code for osmolyte synthesis, late embryogenesis abundant

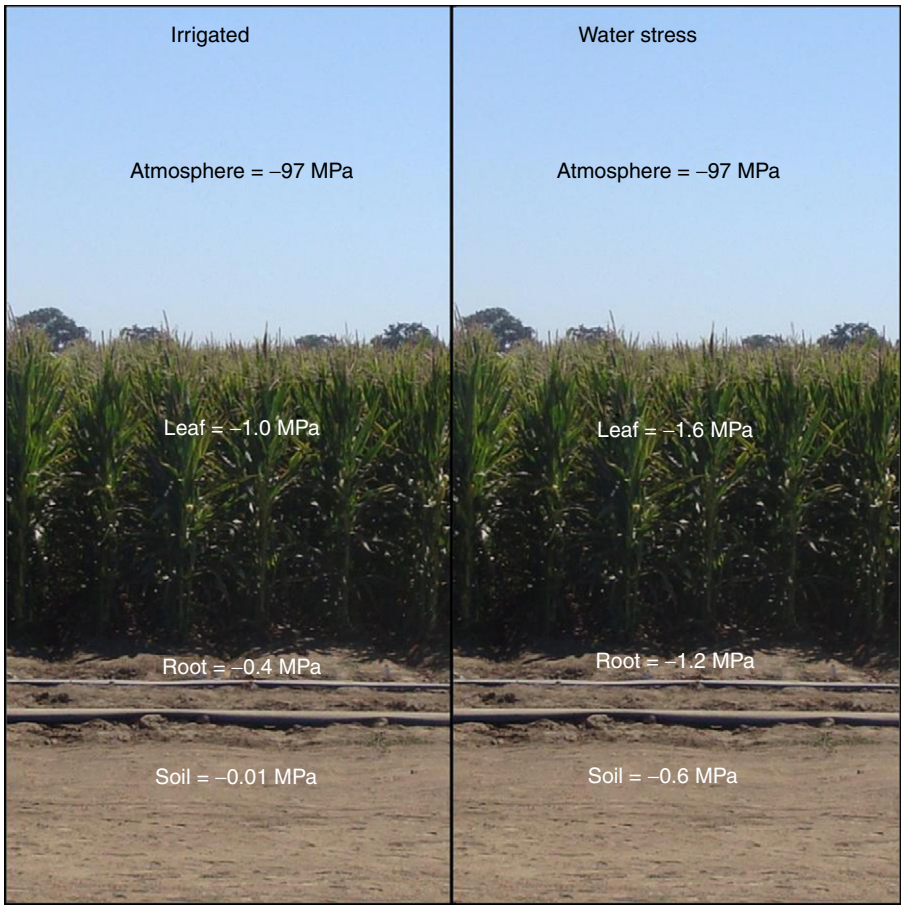

Figure 1 Differences in water potential in the soil-plant-atmosphere continuum under irrigated and water stress conditions in a field.

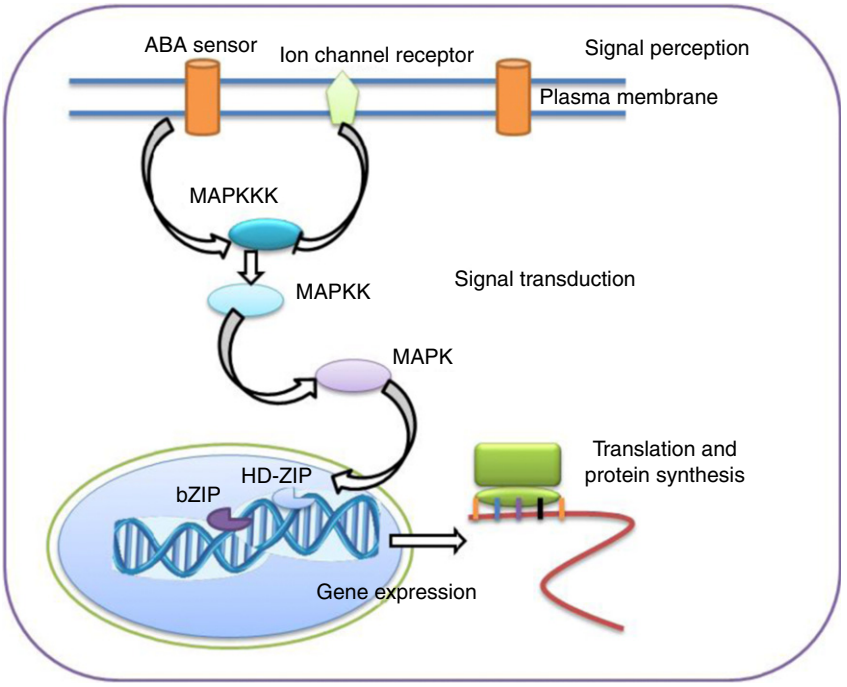

Figure 2 Signal perception, signal transduction, gene expression, and translation in plants.

(LEA) proteins, aquaporins, signaling molecules, and transcription factors (regulate expression of multiple genes) have commonly been detected in plants under drought stress (Bhargava and Sawant, 2013). Transcription factors that bind to the promoter region of other stress-response genes and regulate their expression can be produced (**Figure 2**). Several families of transcription factors, such as bZIP, AP2/ERF, HD-ZIP, MYB, NF-Y, and ZPT2, are known to regulate drought-specific gene expression (Bhargava and Sawant, 2013).

What changes do these genes produce in the plant? In response to stress signal transduction, several genes are differentially expressed, resulting in changes in stress-related metabolic pathways. Global gene expression is typically studied using microarrays (using complementary deoxyribonucleic acid (c-DNA) copies of messenger ribonucleic acid (mRNA) as a target for DNA probes) or more recently using RNA-sequencing (RNA-seq) analysis. Gene-expression changes under water stress in maize using RNA-seq analysis have indicated that more changes are generally seen in reproductive tissue than in vegetative tissue (Kakumanu *et al.*, 2012). This agrees with the observations that reproductive tissues are more sensitive to drought stress than vegetative tissue in maize. Downregulation of starch and sucrose biosynthesis genes and a host of genes encoding cell cycle progression and upregulation of genes encoding ABA biosynthetic pathway have been observed in maize (Kakumanu *et al.*, 2012). In response to water stress, gene-expression changes affect several stress-related metabolic pathways that result in changes in metabolites in different tissues. When metabolite changes were measured under water stress and well-watered conditions in maize hybrids, amino acids, sugars, and intermediates of the tricarboxylic acid cycle (TCA) cycle were increased under water stress conditions relative to well-watered conditions (Witt *et al.*, 2012). Changes in the amino acids, including proline, histidine, asparagines, tryptophan, and phenylalanine, were increased in all major tissues (Witt *et al.*, 2012).

In soybeans, microarray analysis of soybean leaves under water stress indicated that both transcription factors (DREB, NAC, and ZAT/STZ) and functional proteins (LEA proteins, glycosyltransferases, glycoside hydrolases, defensins, and glyoxalase I family proteins) were upregulated, whereas genes related to hormone pathways and photosynthesis-related genes were downregulated (Le *et al.*, 2012). Metabolite analysis of soybean plants under water stress indicated that accumulation of pinitol, a common osmolyte in legumes, was observed. In addition, accumulation of proline was observed under flowering stage; several changes in the intermediates of the TCA cycle were observed and nitrogenase activity was not altered (Silvente *et al.*, 2012). In rice, the majority of differentially expressed genes under water stress were identified in the leaf tissue at panicle-initiation stage (Wang *et al.*, 2011). Gene ontology revealed that several genes related to the photosynthetic pathway, cell membrane biogenesis, and cell wall modification were downregulated under water stress in rice (Wang *et al.*, 2011). Also in rice, photorespiratory metabolism increased, whereas no changes in Calvin cycle metabolism were noticed under water stress (Lakshmanan *et al.*, 2013).

At the physiological level, water stress can result in both short-term and long-term (acclimation) responses. Short-term responses to water stress include root signaling, changes in xylem conductivity, ABA-mediated stomatal closure, and inhibition of growth (Chaves *et al.*, 2003). Acclimation changes to water stress include osmotic adjustment, reduced leaf area, changes in carbon metabolism (lower photosynthesis and respiration), and changes in source–sink relationships and partitioning (more root or reproductive tissue growth over leaf growth) (Chaves *et al.*, 2003).

Considering the vast extent of research done in the area of water stress-induced physiological changes in plants, the article focuses on changes that affect crop yields. For field crops, timing of water stress is crucial. Maize is most sensitive at flowering stage (Claassen and Shaw, 1970; Boyer and Westgate, 2004; Campos *et al.*, 2006), whereas soybean is most sensitive to water stress between pod formation and pod-filling stages (Manavalan *et al.*, 2009). Rice is most sensitive to water stress during panicle initiation and flowering (Wopereis *et al.*, 1996; Lafitte *et al.*, 2007). The effect of water stress on physiological changes affecting crop yield can be understood from the equation $\text{Yield} = \text{WUE} \times \text{E} \times \text{HI}$ (Passioura, 1996; Blum, 2009), where WUE is water-use efficiency calculated as ratio of biomass produced to transpiration, E is transpiration, and HI is harvest index, calculated as ratio of grain yield to total biomass production.

WUE is affected by processes that affect both biomass production and transpiration in plants (**Figure 3**). Owing to an efficient photosynthetic pathway coupled with lower stomatal conductance in C4 plants, WUE of C4 species is higher than that of C3 species. For example, WUE of maize (C4 plant) is nearly 3–5 times higher than that of soybean and 2 times higher than that of rice (Sadras *et al.*, 2007, FAO report), both C3 plants. WUE of sorghum (C4 plant) is higher than that of soybean due to higher assimilation and lower transpiration rates (lower leaf area and stomatal conductance) in sorghum (Teare *et al.*, 1973). Generally, WUE is higher under water stress than irrigated conditions. Expression of the *Arabidopsis HARDY* gene in rice caused an increase in WUE, more under water stress than well-watered conditions (Karaba *et al.*, 2007). Water stress can affect biomass production, thereby WUE, reductions in green leaf area (Borrell *et al.*, 2000), light capture and radiation-use efficiency (Earl and Davis, 2003), photosynthesis (Shou *et al.*, 2004), and respiration (McCree, 1986). However, water stress can affect transpiration by causing a reduction in total leaf area (Sionit and Kramer, 1977; Sharp and Davies, 1979), stomatal conductance (Davies and Zhang, 1991), and root growth (Sharp and Davies, 1979).

Reduction in transpiration happens due to changes at both leaf (short term) and canopy (long term) levels (**Figure 3**). At the leaf level, reduction in transpiration is mainly brought about by stomatal closure. The hormonal ABA mediation of stomatal closure under water stress is well documented. Water stress is first sensed by roots, with ABA acting as a long-distance chemical carrier to transport the signal of water stress to the leaves (Davies and Zhang, 1991; Comstock, 2002) in plants. The hormone ABA also regulates Ca^{2+} concentration in the cytoplasm of guard cells, which further activates anion channels that efflux K^+ and other anions from guard cells (Mori *et al.*, 2006; Pandey *et al.*, 2007). This results in loss of turgor in guard cells and subsequent stomatal closure.

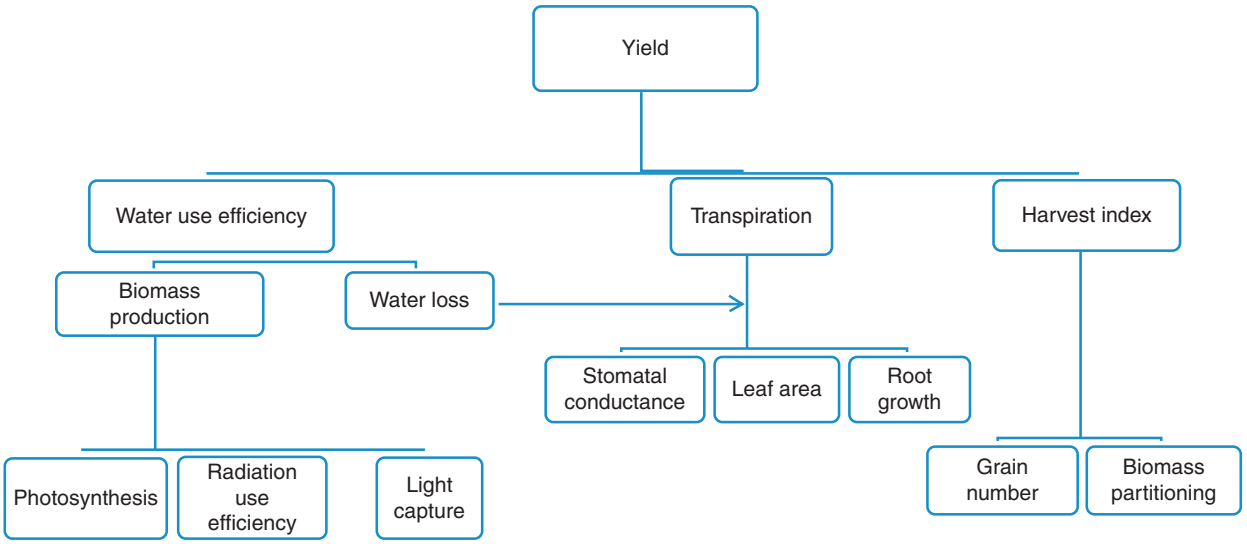

Figure 3 Effect of drought stress on physiological responses related to yield components that affect yield under water stress.

As ABA movement can be a slow process, the signal may take a very long time to reach leaves in tall trees. A different mechanism, namely a drop in hydraulic conductance, was proposed as a nonchemical and relatively rapid signal of water stress in tree species (Saliendra *et al.*, 1995; Comstock, 2002). As described before, long-term responses that result in reductions in transpiration include lowering leaf growth (Boyer, 1970; Sionit and Kramer, 1977; Sharp and Davies, 1979). The primary reason for lower leaf growth under water stress, in spite of increased sugar concentration, appears to be driven mainly by lower turgor in plants (Muller *et al.*, 2011).

Water stress can reduce the harvest index of plants (e.g., maize) likely due to the relatively higher sensitivity of reproductive growth than vegetative growth to water stress. A comparison of old and new tropical maize hybrids, where water stress is common, indicated that harvest index is less stable in the older, less developed hybrids due to lower kernel set (Echarte *et al.*, 2003). Thus, water stress can reduce harvest index by affecting the seed number set by the plant (**Figure 3**). In maize, the setting of the kernel number is affected by the amount of dry matter partitioned to the ear during the critical time – period that brackets silking (Echarte *et al.*, 2004; Tollenaar and Lee, 2006). Selection for drought resistance by imposing water stress during this critical period resulted in hybrids with increased harvest index due to improvement in the amount of assimilates partitioned to the ear (Edmeades *et al.*, 1999). Soybean appears more flexible than maize to responding to water stress, with a close coupling between reproductive and vegetative growth making the harvest index stable under both water stress and irrigated conditions (Spaeth *et al.*, 1984). In contrast, water stress during the grain-fill period increased harvest index in rice by increasing the remobilization of reserves into grain (Yang and Zhang, 2010).

Recently, research is being increasingly focused on the regulation of gene expression by microRNA (miRNA) gene silencing that can affect the pattern of growth in plants as a response to the stress. miRNAs are usually not expressed to directly produce proteins, but their presence can affect the expression from other genes that typically do lead to the production of proteins. The small miRNA sequences target mRNAs to induce cleavage of the mRNAs and repress their translation into proteins. An example is miRNA393, which is involved in lateral root growth development (Chen *et al.*, 2012). Root growth tends to be less lateral and more vertical under drought conditions to enable roots to reach deeper zones for water. The response is mediated by the plant growth hormone ABA in antagonism with auxins. Recent studies indicated that miRNA393 was involved in gene silencing of two auxin receptors, TIR1 and AFB2, required for the inhibition of lateral root growth by ABA (Chen *et al.*, 2012). Another example is miRNA159, which silences several MYB transcriptional factors that positively regulate ABA responses and miR398 which, in turn, targets genes that play a role in scavenging potentially damaging superoxide radicals generated during drought (Bhargava and Sawant, 2013).

So far, the effects of water stress on crops at molecular, metabolic, and physiological scales have been discussed. Luckily, plants have evolved mechanisms to cope with water stress. There are primarily two mechanisms for resisting water stress in crops, viz., dehydration avoidance and dehydration tolerance. Of these two, dehydration avoidance is the main mechanism for drought resistance in the major row crop plants (Blum, 2005). Dehydration avoidance is the capacity of plant to maintain high water status or cellular hydration when exposed to low soil water potentials. In other words, plants avoid exposure to drought or water stress when subjected to low soil water potential. The mechanisms that render dehydration avoidance include lower water loss from crops (via decreased stomatal conductance, leaf rolling, and decreased leaf area), increased water uptake by crops (via deeper root system), and maintenance of water uptake by crops at low soil water potential (osmotic adjustment). However, dehydration tolerance refers to the capacity of plant to function in spite of low water status or cellular dehydration. Dehydration

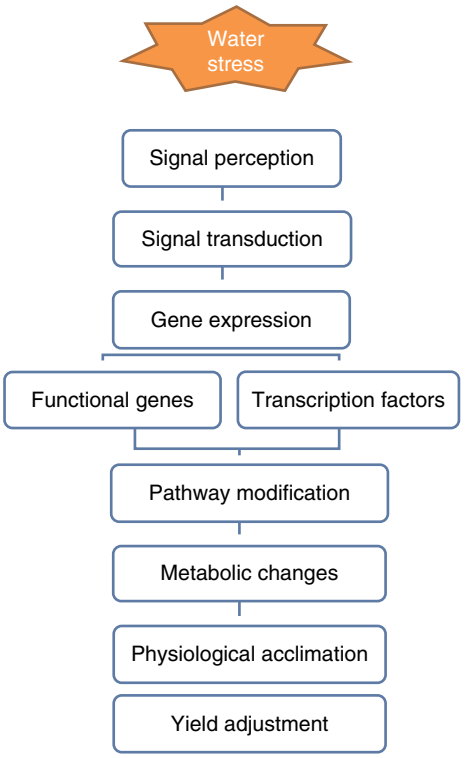

Figure 4 Cascade of responses at the molecular, metabolite, physiological, and agronomic scales in response to water stress in crops.

tolerance is rare in crop plants. It is observed in most seeds, but after germination the trait is normally lost in crops. Dehydration tolerance requires that plants undergo dormant conditions (Blum, 2005).

Starting from the signal perception stage until physiological changes in plants, water stress affects various processes in plants and the cascade of changes results in the final phenotype in which the plant is acclimated to the water stress (Figure 4). These phenotypic changes might help a crop to survive the drought but can affect crop yields. To cope with water stress, crop plants have mechanisms to reduce water loss, maintain transpiration, or continue uptake of water.

Reducing Yield Loss under Water Stress

In this section, three components – WUE, E, and HI and their effect on reducing yield loss under water stress conditions – are examined. An increase in any of the three components can have a positive impact on yield, if the net effect of other components does not change. Increases in WUE without a change in E can arise only if total biomass production or more specifically the rate of photosynthesis increases. Within a crop species, improvement in WUE is mostly due to factors that reduce transpiration (E) because increases in the rate of photosynthesis have not yet been genetically improved through breeding (Earl, 2002; Blum, 2005). If higher WUE due to lower E is a constitutive trait, then the crop may have lower yield when growing conditions provide plenty of water (Condon *et al.*, 2004; Blum, 2009). This is mainly because of the tight link between E and total biomass production under all environmental conditions (Blum, 2009). The penalty under well-watered or irrigated conditions for crops with high WUE can be minimized if high WUE can be triggered selectively under stress. A different term 'effective use of water' was proposed to emphasize the importance of improvement in yield due to increase in transpiration under water stress conditions (Blum, 2009). Maintenance of E under water stress requires either osmotic adjustment and increased root growth or a shift in partitioning of growth from shoot to root. The increase in investment in osmotic adjustment, or deeper root system, can be of no use under well-watered conditions or when water stress is alleviated. In tropical maize improvement, where water stress affects crop production, yield improvement was associated with the improvement in harvest index (Edmeades *et al.*, 1999; Echarte *et al.*, 2004; Tollenaar and Lee, 2006). A combination of higher WUE, lower E, and higher HI has been shown to increase crop yields in rice. When water stress was imposed during grain-fill stage in rice production, WUE increased along with HI, which increased due to an increase in mobilization of reserves to grain (Yang and Zhang, 2010). Thus, responses that improve water uptake or reduce water loss (in combination with improved remobilization of sugars) can result in lower yield losses under water stress conditions.

Industry Efforts to Develop Drought-Resistant Hybrids/Varieties

In the last decade, molecular breeding and biotechnology techniques have been used by industry to develop hybrids with increased resistance to water stress. Molecular breeding involves identifying regions of the genome (e.g., quantitative trait loci (QTLs)) that are related to favorable traits under water stress and then pooling genes together to develop new hybrids or varieties. A genetic linkage map of chromosomes showing the location of favorable genes (QTLs) is developed and, based on the map information, markers (short DNA sequences) that are closest to the gene are identified. Several QTLs are combined by traditional breeding and crossing techniques and markers are used to quickly identify the best combination of QTLs (genes). As markers can be identified from any tissue (seeds or seedlings) and are not influenced by environment, the process of selection can be efficient and rapid. Therefore, new hybrids or varieties can be developed in a shorter period of time than by traditional breeding methods. The limitation of this method is that only traits that are present in a species genome that can be crossed with commercial varieties or inbreds can be introduced into the new hybrids or varieties. However, biotechnology or genetic engineering can aid in introducing new and favorable genes from theoretically any organism or designed synthetically, thus broadening the diversity of source genes. The process involves combining appropriate genes with appropriate gene expression elements and using a variety of processes (including the bacterium *Agrobacterium tumefaciens* transfection or microparticle bombardment) to introduce the engineered DNA into plant cell genomes.

Figure 5 Ears of non-genetically modified organism (GMO) hybrid (top) and Monsanto DroughtGard hybrid (bottom) tested in Kansas, US, where water stress is common.

Since 2011, three drought-tolerant maize hybrids were released by industry using traditional breeding, molecular breeding, or biotechnology. These include Agrisure Artesian™ from Syngenta, Optimum® AQUAmax® from Pioneer, and Genuity® DroughtGard™ from Monsanto (Figure 5). Drought-tolerant hybrids were developed by Syngenta and Pioneer using traditional and molecular breeding technology, whereas the Monsanto drought-tolerant hybrid was developed by combining a biotechnology-derived drought-tolerant trait (Castiglioni *et al.*, 2008) and the best plant germplasm selected through advanced breeding. In regard to the use of biotech traits to manage drought stress, it is important to realize that the earlier developed biotech traits that protected plants against root-eating insects and weeds provided a degree of protection against drought stress by preventing insects or weeds from interrupting root access to the available soil moisture. Thus, these traits can be stacked with drought tolerance traits and germplasm to obtain an additive effect. Moreover, it is recognized that the use of optimal agronomic practices (including conservation tillage practices and appropriate crop rotation) in addition to the best germplasm (including the molecule breeding mentioned above) along with a multitude of biotech traits is required to have the most desired effect.

In conclusion, water stress is a major factor affecting food production due to insufficient rainfall and competition for fresh water from population and industry growth in several regions of the world. When crop plants are exposed to water stress, a series of molecular, metabolic, and physiological changes happen that lead to a desired phenotype that further aids in limiting crop loss. Several years of scientific advancement in the knowledge on crop water stress coupled with the importance of combating water stress in agriculture has enabled the seed industry to develop drought-tolerant hybrids or varieties to aid farmers. Future technologies include combining the optimal agronomic practices, use of best germplasm, and a multitude of biotechnology-derived traits to combat water stress.

Plant Biotic Stress: Weeds

C Preston, University of Adelaide, Adelaide, SA, Australia

© 2014 Elsevier Inc. All rights reserved.

Glossary

Crop mimicry The physical resemblance of the weed to the crop at some growth stage, which allows the weed to avoid eradication.
Dormancy The ability of a seed to not germinate even though suitable environmental conditions are available.
Herbicide resistance The inherited ability of a plant to survive and reproduce following exposure to a dose of herbicide normally lethal to the wild type.
Herbicide-tolerant crop Crop that has been bred, through conventional or genetic engineering, to have resistance to a herbicide that would normally harm the crop.
Lay-by herbicide application Residual herbicide applied to soil after the crop has established to control further weed germination.
Nonselective herbicide Herbicide that will control most plant species.
Postemergent herbicide Herbicide applied to the target weed after it has emerged.
Preemergent herbicide Herbicide applied before germination of the target weed.
Residual herbicide Herbicide that remains active in the soil for some time after application.
Seed destructor Equipment attached to the back of a harvester that destroys weed seed exiting the harvester.
Selective herbicide Herbicide that can be applied to both crop and weed without harming the crop.
Solarization The use of plastic sheeting to heat the soil surface using sunlight in order to kill weed seeds.
Weed biocontrol The introduction into the environment of a natural enemy of a weed species in order to control the population of the weed.

Introduction

Weeds are one of many biotic stresses on plants in agriculture. The move toward more managed agricultural systems with greater mechanization over the past two centuries has increased the importance of weeds as a constraint on agricultural production. Weeds can have a substantial impact on agricultural production. For example, Pimentel *et al.* (2001) estimated weeds caused losses of more than US$100 billion to agriculture production in just six countries.

Weeds – A Definition

There are many definitions for a weed. The one most often used is 'a plant out of place' or 'an unwanted plant.' From an agricultural perspective, a weed may be more narrowly defined as a plant that has an impact on agricultural production.

Although all plant species may be undesirable in specific locations, some plant species are more likely to occur as troublesome weeds than others. Baker (1974) provided a list of traits that were frequently associated with weedy species in agriculture. These traits are listed in **Table 1**, reorganized by the stage of the plant life cycle. There has been much discussion since about these characteristics and whether other characteristics should be included. There have also been attempts to predict weed species from functional groups (Reichard and Hamilton, 1997).

Many agricultural weeds tend to be r-selected species (Sutherland, 2004). These are species that produce numerous seeds with little maternal investment in each individual seed, rather than fewer, larger seeds. This allows populations to increase rapidly under suitable conditions. In general, weeds of annual crops tend to be annual species, whereas there are far more perennial species that are weeds of pastures and grazing lands (Maillet and Lopez-Garcia, 2000).

Crop mimicry is a trait common to several major weeds of agriculture. Crop mimicry is normally defined as physical resemblance of the weed to the crop at some growth stage, which allows the weed to avoid eradication. It is likely crop mimics originally evolved in response to selection pressure from hand weeding. A broader definition of crop mimicry includes similarity in life-history traits that allow the weed to germinate and produce seed at about the same time as the crop. For example, in *Echinochloa crus-galli* var. *oryzicola* in California crop mimicry results in the weed seed contaminating crop seed used for seeding subsequent crops of rice. This has allowed the weed to rapidly spread through the rice producing areas of California (Barrett, 1983).

Major weed species are typically well adapted for dispersal. Seed of some weed species, such as *Conyza canadensis*, are dispersed across locations by wind (Dauer *et al.*, 2007). However, other weed species have adaptations that allow them to be dispersed to other agricultural sites. These include the ability to pass intact through livestock, attaching to the outside of livestock or being of similar size to the harvested grain. The frequently disturbed nature of most agricultural ecosystems aids dispersal of weeds by providing numerous sites for germination.

Seed dormancy, the ability of seed to remain alive in the soil, but not germinate, can be an important characteristic for weed species. Seed dormancy allows weed species to survive through unfavorable conditions and to germinate when conditions are suitable. It also allows weed species to survive control actions. Seeds may have after-ripening dormancy, which inhibits germination for a period after the seed is first mature. Other forms of dormancy involve pods or hard seed coats that inhibit access of water into the seed. These will have

Table 1 Characteristics frequently associated with weedy species by stage of plant life cycle

Component of life cycle	*Characteristic*
Germination	Ability to germinate in many environments Discontinuous germination and seed longevity
Growth	Short juvenile phase Ability to compete through growth patterns or chemicals
Reproduction	Self-pollinated, or where cross-pollinated wind or nonspecialized pollinators are used Continuous seed production as long as conditions permit High seed production under favorable conditions Produces some seed under a wide variety of conditions For perennials, ability to reproduce from fragments Has adaptations for short- and long-distance dispersal

Source: Adapted from Baker, H.G., 1974. The evolution of weeds. Annual Review of Ecology and Systematics 5, 1–24.

to be breached before the seed can germinate. Seeds may also contain chemical germination inhibitors that need to be leached from the seed before it is able to germinate. Burial of seeds can induce secondary dormancy, which will persist until the seed is exposed to light or the seed dies. Not all weed species rely on dormancy to aid their persistence (Finch-Savage and Leubner-Metzger, 2006). Some species have short-lived seed banks and rely on continued invasion of wind-borne seed.

Few widespread weed species have specialized pollinators. Specialized pollinators restrict the geographical extent of the plant species. Many weed species are able to self-pollinate. This allows a new infestation to start from a single seed germinating. However, self-pollination restricts the genetic diversity within populations. Weeds that outcross often use wind as a means of dispersing pollen. Wind can disperse pollen to large distances and allows ready mixing of alleles within and between populations. A small number of weed species rely on bees as a vector of pollen. These weeds are particularly common in agricultural landscapes where the honey bee is used to pollinate crops.

Weed Impacts in Agricultural Systems

Weed species can have a variety of impacts in agricultural systems. The most obvious is loss of yield caused by weed competition for space, light, and nutrients. In annual crops, the amount of yield loss varies widely. Yield loss is impacted by the density of the weed population and the competitive ability of the crop. Yield loss is also impacted by the relative emergence times of the crop and weed species, with weeds emerging with the crop, or shortly afterwards, being the most competitive (Zimdahl, 2004).

In pasture and rangeland systems, weeds occupy space that could otherwise be occupied by more valuable pasture species. In this way, weeds reduce pasture productivity. Weeds may also have allelopathic impacts, whereby the weed either secretes chemicals into the soil through the roots, or chemicals are leached from dead leaf tissue into the soil, thus inhibiting the growth of nearby plant species (Qasem and Foy, 2001). In permanent plantings, weeds typically reduce productivity by competing for water and nutrients. This is particularly important in dryland crops. With short crop species, weeds may also grow taller than and shade out the crop.

In addition to yield loss, weeds may also result in reductions in quality of the end product. Such reductions in quality can come about due to contamination of the harvested product. For example, canola (oilseed rape) has low erucic acid and low glucosinolate content. Contaminating weed seeds from Brassica species, such as *Raphanus raphanistrum*, that have high erucic acid and glucosinolate content in the grain harvest may make the grain unsuitable for use (Blackshaw *et al.*, 2002). Likewise, contamination of weeds that are poisonous to stock in hay may make the hay unsalable. The presence of spiny weed seeds in dried grape production will downgrade the end product.

Apart from direct contamination of weed material in the end product, weeds can reduce the end quality of produce through taint. For example, dairy cattle grazing on certain species may result in undesirable compounds in milk, which alter the flavor or smell of the end product. Likewise, cattle grazing on *Allium ursinum* will accumulate compounds in their milk that results in unwanted flavors (Naylor and Lutman, 2002).

A third way that weeds impact agricultural activities is through reduction in access to grazing. In addition to utilizing space and resources that could be otherwise used by valuable pasture plants, weeds may inhibit stock from accessing pasture. Typically spiny plants, such as thistles or spiny shrubs, like *Ulex europaeus*, can reduce access of stock to valuable pasture growing around the weed species.

Another weed impact in grazing systems is where weed species cause direct damage to the stock. Poisonous species growing in pasture may kill stock or harm their health, reducing growth and longevity (DïTomaso, 2000). There are many examples of poisonous weeds. Some species are more poisonous to certain stock, for example *Echium plantagineum* can be grazed by sheep, but not by horses. Other species have sharp spines or seeds that can cause damage by sticking in the mouth, nose, or eyes of stock. In addition to the damage such spines do directly, they can be sites of infection. Weeds that have spiny seed, such as *Bromus* spp., *Hordeum* spp., and *Erodium* spp. can also puncture the skin of grazing animals causing damage to the pelt, or become entangled in wool causing vegetable fault (Bourdôt *et al.*, 2007).

Lastly, weeds may interfere with farm activities. Climbing weeds in orchards or vineyards may reduce access to fruit and slow picking of the product. Weeds with spines can cause damage to workers hand picking fruit and vegetables, slowing harvesting operations. Weeds can also interfere with mechanical field operations. For example, viney weeds present at sowing of the crop can entangle in the seeding equipment, slowing the seeding process. Weeds that grow as thickets, such as *U. europaeus*, may impede access to certain parts of the farm, reducing the ability to effectively manage the land (Clements *et al.*, 2001).

Weeds can also harbor pests and diseases and make management of these pests more difficult. For example, many broadleaf weed species are alternative hosts for polyphagous insect pests of crops and can maintain populations of the insect pest when the crop is not present (Norris and Kogan, 2005). In permanent plantings, broadleaf weeds hosting insect pests can result in increased populations of the pest during the early part of the season resulting in increased insect damage and more difficulty managing the pest. Many weeds that are related to crops, and some that are not, are alternative hosts for plant pathogens. For example, grass weeds are hosts to many cereal root diseases, as well as leaf diseases, such as rusts. *Berberis vulgaris* is an alternate host for the wheat stem rust, allowing sexual recombination that does not occur on wheat. The presence of these species in the environment increases the size of the pathogen population and can have the undesirable effect of increasing the risk of recombination within the pathogen to generate isolates with broader virulence toward existing resistant cultivars (Kolmer, 2005).

Weed Management Practices

Weed management typically aims to reduce the incidence of weeds in the crop or pasture to the point where they cause no or minimal damage. Often there has to be a compromise between the cost of weed management and the amount of damage caused, so that weeds are rarely eradicated from agricultural land. There are numerous practices that are used for weed management and implementation of these practices is influenced by their effectiveness, cost, time, availability of equipment, and technical knowledge of the manager.

In early agriculture, weed management was mainly through hand weeding. As time went on, mechanical weed management practices were developed, initially using animal power that replaced hand weeding. With better understanding of the biology of weed species, cultural practices were employed. The advent of the industrial revolutions saw the first chemical weed control practices, which have grown rapidly in importance since World War II. In the twentieth century, biological control was targeted for weed management.

In recent times, chemical weed control has become increasingly used as the main weed management practice in crop production in both developing and developing countries. However, nonchemical practices are still widely used in developing countries and are becoming adopted again in developed nations following problems with chemical control practices.

Mechanical weed controls include cultivation, hand rouging, mowing, mulch, and recently developed mechanical seed removal practices. The latter typically use powered equipment to destroy weeds or reduce their impact on production.

Weed management by cultivation involves the disturbance of soil with a mechanical implement that uproots the weed or severs the roots from the tops. There are numerous types of cultivation equipment and the amount of soil disturbance of the equipment used varies. As a general principle, the more soil disturbance by the equipment, the greater the amount of weed control that will result. Aggressive cultivation implements, such as rotary hoes, tend to pulverize the soil, and destroy any plants present. Moldboard and disc plows fully or partially invert the soil and bury the weeds and any seeds present on the soil surface. Blade plows are used to cut the roots from the tops to kill weeds.

Cultivation is used to control weed growth before seeding an annual or perennial crop, so the crop seed is planted into a seed bed free of weeds. After the primary cultivation event, there may need to be secondary cultivation to break up clods and provide an appropriate seed bed for seeding the crop. Shallow working cultivation equipment, such as harrows, can also be used to lightly bury seed and stimulate germination. Many broadleaf weed seeds are stimulated to germinate by light and so are promoted by cultivation (Juroszek and Gerhards, 2004). Cultivating at night can reduce their emergence. Cultivation may also be used between the rows of crops to reduce weed growth once the crop has established. Cultivation causes damage to soil, resulting in soil erosion, compaction and other problems. For this reason, and as a result of increased costs, the amount of cultivation in many agricultural systems has declined in recent decades and cultivation has been replaced by other practices (Chauhan *et al.*, 2006).

Hand rouging is the selective removal of weeds by hand during the crop growing phase. Hand rouging can involve the use of simple tools like the hoe and is most effective when there are few weeds present in the crop. It is still used widely in developing countries and occasionally in developed nations, particularly in organic production systems. The increasing cost and lack of availability of farm labor has seen a decline in hand rouging.

Mowing and slashing are typically used to reduce weed height rather than to remove weeds. They are effective practices, if timed correctly, in reducing weed seed set in pasture systems. Hay production is also used as part of a rotational strategy to reduce grass weed numbers in annual crop rotations. To be effective, mowing or slashing needs to be conducted after the weeds have flowered, but before any seed is set. To be effective as a weed management strategy, a follow up treatment is often required (Donald, 2006).

Mulch is the application of material to soil in order to stop weed seeds from germinating. Mulch may be organic material or made from plastic. Mulches prevent light from reaching the seed and may also provide a physical barrier to the movement of water to the seed. Where mulches are made from allelopathic material, such as rye straw, chemicals leached from the mulch may aid in weed management (Teasdale and Mohler, 2000). Mulches lose their utility as they break down and require frequent replacement. A variation on mulch is solarization, where plastic sheeting is spread on the soil surface.

Sun passing through the sheet heats the soil surface and kills weed seeds (Horowitz *et al.*, 1983).

Recently in Australia seed destruction practices have been employed to destroy weed seed that is present at harvest. These practices include the chaff cart that is towed behind the harvester and collects the fine or chaff fraction of the crop residue exiting the harvester. This fraction contains some of the weed seed that enters the harvester front, but would otherwise be returned to the field. The chaff can then be removed from the farm or burnt to destroy weed seed. Another device is the seed destructor. This device again collects the chaff fraction, but in this case pulverizes the material destroying any weed seed and spreading the material back on the field. Other devices concentrate the crop residue into rows that can be burnt later to destroy weed seeds (Walsh *et al.*, 2013).

Cultural weed management practices include crop rotations, competition, water management, and grazing. Weeds that are related to the crop frequently have an advantage when that crop is grown. This is because control tactics are less successful in controlling close relatives. Examples include grass weeds in cereals where crop mimicry allows grass weeds to survive many practices that control broadleaf weeds. Rotating between cereal and broadleaf crops can change the selection for crop mimics and help reduce their impact (Sosnoskie *et al.*, 2006). Likewise, perennial weed species often infest pastures, but are less common in annual crops as a result of the continual disturbance in the latter. Rotation between pasture and crop production can change the conditions favoring perennial species, reducing their numbers.

Competition aids weed management by reducing the growth and seed production of weed species. Competition for space is widely used in pasture management and it is well known that many weed species germinate in gaps in pasture stands (DiTomaso, 2000). Growing vigorous pasture stands will reduce the ability of weed species to germinate and establish in the pasture. Likewise, crop competition can be used in annual crops to reduce the impact of weeds, either through growing more competitive crop species or increasing the crop seeding rate where that can be an effective practice (Vandeleur and Gill, 2004).

Crops, pasture species, and weeds all require water to grow. In irrigated farming systems, it is possible to change the way water is delivered to favor the crop species. For example, in perennial plantings a change from flood irrigation to drip irrigation targets the water more effectively to the crop. This changes the area over which weeds can compete for water from the whole field to the area under the drippers. An alternative use of water is in rice production. Rice is tolerant to flooding and this can be used to control weeds that are not tolerant of flooding. When and for how long paddy fields are flooded can greatly alter weed infestations (Rao *et al.*, 2007).

Grazing is frequently used as a practice to manage weeds. Grazing is most effective for weed management when used in conjunction with other weed management practices. Grazers rarely consume unwanted plants only, so relying on them to just consume weeds is unlikely to be effective. Short periods of heavy grazing can be used to reduce the competitiveness of weeds in pasture situations, which, if followed by periods where the pasture species are allowed to recover from grazing, can be used to reduce the biomass of weeds (Rook *et al.*, 2004). Grazing can also be used in situations where crops are grown, so long as the crop plants are less attractive to the grazing animals than are the weeds. Grazing to reduce grass growth in vineyards or orchards is an example.

Biological control, or biocontrol, is the deployment of biological organisms to control weeds. Biocontrol may be the only cost-effective management option for widespread weeds in permanent plantings, pastures or grasslands that are difficult to otherwise control. Biocontrol is predicated on most weeds being alien species and separated from their natural enemies that would normally keep weed populations in check. The practice involves the use of a specific natural enemy or enemies of the weed species, typically an insect or a pathogen, that affects growth and seed production of the weed species. It is important that the agent does not cause local extinction of the weed species, because then the agent will also become extinct. Biocontrol is typically less effective in highly disturbed systems, such as annual crops, because the disturbance reduces the population of the agents. Biocontrol has been employed against many weed species, the most famous case being the control of *Opuntia* spp. in Australia by *Cactoblastis cactorum*. The benefit of biocontrol is that once the agent has been released and has established, little additional management is required. The agent will, over time, reduce the population of the weed to a low level (McFadyen, 1998).

Chemicals, called herbicides, are a very common way of controlling weeds in agricultural systems. Herbicides are used widely in annual crops and in vineyards and orchards. Herbicides are also used in pastures as a weed control method, but typically there is less herbicide use in pastures than in crops. Herbicides may be natural compounds, but most often they are synthetic compounds specifically chosen because of the weed spectrum they control and their safe use in crops (Cobb and Kirkwood, 2000).

Herbicides can be applied to bare soil to inhibit weeds germinating. These are known as preemergent herbicides. Preemergent herbicides are often applied just before or just after crop seeding to reduce the number of weeds that may emerge and compete with the crop. They can also be used in some circumstances after the crop has established and in perennial crops as lay-by applications. Preemergent herbicides have residual activity in the soil persisting for some period after application and may control weed germination for weeks or months. For this reason, they are also called residual herbicides.

Postemergent herbicides are applied after the weed species have germinated. These herbicides may or may not have residual activity in the soil. Postemergent herbicides are more flexible in use than preemergent herbicides. This is because they do not have to be used unless the weed is present.

Some herbicides are able to be used in certain crops without damage to the crop. These are known as selective herbicides. Typically, the herbicide is selective because the crop species is able to rapidly degrade the herbicide before the herbicide damages the crop. This often means that weed species that are related to the crop species are unable to be controlled by the herbicide.

A smaller number of herbicides kill, or damage, almost all plant species. These are called nonselective herbicides. These herbicides cannot be used over the crop and are used before

sowing the crop or between the crop rows. Nonselective herbicides are useful because they control most unwanted vegetation, but are less versatile than selective herbicides. This is because they can only be applied when the crop is not present or where the crop can be physically protected from the herbicide through use of a shroud.

The majority of herbicides inhibit a single enzymatic process within the plants that causes the plant to die. This is known as the herbicide target site. Inhibition of this enzyme may lead directly to death of the plant, or the plant may die from secondary reactions that occur as result of inhibiting that enzyme. It is possible to place herbicides into groups based on how they kill plants. This is known as the mode of action for that herbicide. The international herbicide resistance action committee describes 19 different herbicide modes of action as well as a small number of herbicides where the mode of action is not known (Menne and Köcher, 2012).

In the past two decades there has been the development of herbicide-tolerant crops. These are crops that have been bred to be tolerant of herbicides that would normally damage that crop species. Herbicide-tolerant crops can be useful in the control of weed species that would otherwise not be controlled. Several approaches have been used to develop herbicide-tolerant crops. These have included mutagenesis to create resistant target enzymes, crossing with species that have resistance to the herbicide or through genetic engineering to introduce new genes that provide resistance to the herbicide (Green, 2011).

In certain cropping systems, there has been widespread adoption of herbicide-tolerant crops. Examples include canola production in North America and Australia, soybean and corn production in North and South America, and cotton production in North America and Australia. The main reasons for adoption of herbicide-tolerant crops are to manage otherwise difficult to control weeds and to simplify the production system (Green, 2012).

Evolution of Avoidance of Weed Management

One of the consequences of adopting weed management tactics is that avoidance of the management tactic will arise. Such changes can occur because all of the weed species that are easily controlled by the management practice are removed, leaving the more tolerant weed species behind. An example would be selective grazing by animals removing the palatable species, but leaving behind the unpalatable ones to increase in number (Popay and Field, 1996). The more effective the weed management measure, the more rapidly the change will take place.

An example of avoidance in weed management is weed species shifts that have occurred as the result of adoption of herbicides. For example, from 1950s to the 1960s there was an increase in importance in grass weeds in UK cereal production (Fryer and Chancellor, 1970). The likely reason was the widespread use of herbicides that controlled broadleaf weeds in cereals during the 1950s and 1960s. The control of broadleaf weeds provided an opportunity for grass weeds to invade. Species shifts can occur more than once if weed control practices change. In the UK, the advent of effective grass herbicides in the 1970s has seen a decline in grass weed abundance in cereal crops since that time (Potts *et al.*, 2010). A weed species shift has been observed over a shorter time period in the United States with the rapid adoption of glyphosate-resistant crops (Webster and Nichols, 2012).

Another form of avoidance is where a species becomes resistant to the control method. One example is the evolution of biotypes of *Poa annua* and *Plantago vulgaris* for resistance to mowing. Continual mowing of grass swards over a long period has selected for more prostrate individuals with shorter inflorescences (Warwick and Briggs, 1979). Another example has been the selection of early maturity in *Hordeum glaucum* in Tasmanian alfalfa fields. A long period of continuous alfalfa mown every year resulted in the evolution of a population that matured early and shed seed before the mowing operation (Purba *et al.*, 1996).

The most well-known example of weed resistance is resistance to herbicides. For herbicides, resistance is defined as "the inherited ability of a plant to survive and reproduce following exposure to a dose of herbicide normally lethal to the wild type" (WSSA, 1998). Weed resistance to herbicides was first documented in 1953; however, the first example to have significant consequences was resistance to the triazine herbicides in corn production, starting in the 1980s. Resistance has evolved in at least one weed species to herbicides from 16 of the 19 different modes of action (Powles and Yu, 2010).

Herbicide resistance evolves because herbicide use selects individuals within the population that carry rare alleles that allow them to survive the herbicide application. At the same time the vast majority of the population is killed by the herbicide. If the surviving plants are allowed to reproduce, the frequency of individuals within the population carrying resistance alleles increases. Continual use of the same herbicide or of herbicides with the same mode of action selects for a population with a high frequency of individuals with resistance to the herbicide resulting in failure of the herbicide to control the population.

Herbicide resistance is at its worst in developed countries, with USA, Canada, and Australia having the greatest number of weed species with resistance. This is because weed management in agriculture in developed nations is more dependent on herbicides. However, herbicide resistance also occurs in developing countries and by 2013 resistance was reported to 217 weed species in 61 countries (Heap, 2013). Often weeds evolve resistance to a single herbicide mode of action; however, recently, more weeds with resistance to multiple herbicide modes of action are being reported. For example, one population of *Lolium rigidum* in Australia is resistant to seven herbicide modes of action (Heap, 2013).

The widespread adoption of glyphosate-tolerant crops in North and South America has led to the evolution of glyphosate-resistant weeds over large areas of these cropping systems. In these areas, the adoption of crop rotations entirely dependent on glyphosate for weed control has led to the rapid selection of glyphosate-resistant weeds (Green and Owen, 2010).

In several agricultural systems, such as wheat production in Australia and cotton production in the United States, the evolution of widespread herbicide resistant weeds has led to a reconsideration of weed management strategies based solely

on chemical control. In Australian wheat production, a number of alternative practices for control of major weeds are being adopted (Walsh *et al.*, 2013). In US cotton production, the reintroduction of tillage and increased hand rouging of weeds is taking place (Culpepper *et al.*, 2010).

Plant Cloning: Macropropagation

RRB Leakey, James Cook University, Queensland, Australia

© 2014 Elsevier Inc. All rights reserved.

Glossary

Phase change The transition in plants from a juvenile vegetative state to the sexually reproductive state.
Physiological aging Aging attributable to the loss of vigor and a decline in physiological activity. This is one of the three forms of aging seen in trees.
Plagiotropic Nonvertical plant growth.
Plasmodesmata Microscopic channels for transport and communication between cells in plant tissues.
Scion A piece of stem with buds from a large mature plant, which is grafted to the shoot of a young plant with its own roots.

Introduction

Cloning is a process by which individual organisms are multiplied asexually – a process of vegetative regeneration or reproduction (Longman, 1993). Consequently, the individual plants forming a clone are genetically identical. Cloning can be both a natural and an artificial process. The natural process embraces the lateral spread of creeping plants by their shoots or roots, and the production of new plantlets from dispersed, separated, or fragmented plant parts. Vegetative regeneration is a common characteristic of undesirable and invasive weeds. It is often associated with organs that have evolved as part of a perennial life form involving specialized storage organs (e.g., tubers, bulbs, rhizomes, etc.). However, vegetative regeneration also has advantages in agriculture: first, some of the specialist storage organs are good sources of carbohydrates for human food and so become crops – potatoes, yams, cassava, onions, etc. In addition, the capacity to regenerate asexually can be used to multiply these crops without the alteration of their genetic characteristics during the segregation phase of sexual reproduction. This also applies to many trees and other plants which can be artificially regenerated by stem cuttings, grafting, budding, or marcotting (air layering).

The development of clonal crops producing specialist storage organs will not be considered further here as the process just involves the selection of the best individuals from natural populations or from the progeny of breeding programs. Instead, it will be examined as to how the artificial process of vegetative regeneration is used by agriculturalists, horticulturalists, and foresters in domestication programs to capture and multiply individual genotypes, and hence to produce cultivars and clones of crops that would not normally be multiplied clonally. This is especially important in trees as less progress has been made in tree crop domestication because of: their relatively long generation times (approximately 3–20 years); irregularity in flowering and fruiting due to climate and physiological rhythms; predominantly outbreed nature with low heritability in many traits, and high genetic diversity of base populations.

In this Encyclopedia two articles examine the processes of vegetative regeneration. One involves the relatively new processes of micropropagation which have arisen from the development of modern biotechnology, and the other, this article, which involves the more traditional techniques of macropropagation.

The Use of Macropropagation

The use of cloning is not a new concept associated with the advent of biotechnology. It has been used mainly in perennial crops for thousands of years by agriculturalists and horticulturalists, and used by foresters for at least 800 years (Hartmann *et al.*, 2010; Chapter 40). This is because there are many instances when multiplication by vegetative means is a more appropriate strategy than multiplication by seed (Mudge and Brennan, 1999). It is the capacity to rapidly develop cultivars by clonal selection and propagation that is especially important in the domestication of food and nonfood crops from trees, shrubs, and woody vines (Leakey, 2012). However, the techniques are not exclusively used to multiply woody plants, as many ornamental herbaceous plants are also propagated vegetatively because the techniques are simple, inexpensive, and result in high rates of multiplication. This article focuses on woody perennials as they are the most challenging subjects for vegetative propagation.

Vegetative propagation has the advantage that it captures nonadditive as well as additive gene effects, but it should be noted that vegetative propagation only replicates existing genetic traits within newly formed plantlets and does not in itself improve the genetic quality of the material being propagated.

There are a number of important practical issues that need to be resolved when making the decision to use vegetative propagation (**Table 1**). These are associated with the use of appropriate technologies, techniques, and plant tissues (**Table 2**) to ensure the efficient and wise use of clones for improved and sustainable production (Longman, 1993; Leakey and Simons, 2000), as part of a wise strategy for tree domestication (Leakey and Akinnifesi, 2008) for the delivery of agroforestry and multifunctional agriculture.

Techniques of Macropropagation

All techniques of macropropagation are dependent on the capacity of undifferentiated meristematic cells to divide and differentiate to form new shoots or roots (Hartmann *et al.*, 2010). Although it is sometimes possible to develop new shoots from root tissues, it is generally easier to develop new roots from shoot tissues.

Table 1 When to use vegetative propagation as a tool in tree domestication

When elite trees have a rare combination of a few inherited traits.
When there are many desirable traits for simultaneous selection.
When high uniformity is needed to ensure profitability and to meet market specifications.
When the products have a high value that can justify the extra expense.
When the trees to be propagated are 'shy' seeders and the material for propagation is scarce.
When the timescale required does not allow progress through the slower and less efficient process of breeding.
When seeds have a low level or short period of viability.
When the knowledge of proven traits is acquired through long-term experiments or the traditional knowledge of local people.

When does vegetative propagation provide a viable alternative to propagation by seed in forestry and agroforestry in the tropics and sub-tropics? In: Wolf, H., Arbrecht, J. (Eds.), Problem of Forestry in Tropical and Sub-tropical Countries – The Procurement of Forestry Seed – The Example of Kenya. Ulmer Verlag: Germany, pp. 67–81.

Grafting and Budding

Grafting and budding techniques are especially important in the vegetative propagation of woody plants that have a long period (3–20 years) of juvenile vegetative growth before becoming sexually mature and capable of flowering and fruiting. This is because mature tissues of trees seem to be very difficult to propagate by the formation of roots at the base of a piece of stem (a stem cutting). Consequently grafting and budding techniques are used in this situation as they do not involve root formation. Instead, they are dependent on the fusion of tissues from two different shoots (Hartmann *et al.*, 2010). In this way, grafting and budding form multiple copies of large mature tree on seedling rootstocks. Grafting and budding techniques involve the placement of a severed piece of shoot (a scion), or an axillary bud, from the chosen tree in immediate contact with similar tissues on the stump or rootstock of an unselected tree, such that the tissues grow together, fuse, and the buds on the attached scion grow out to form a copy of the chosen tree. A number of well-known techniques have been used and practiced for thousands of years – known as cleft grafts, approach grafts, whip/tongue grafts, and side veneer grafts (Hartmann *et al.*, 2010).

The success of all these techniques depends on the juxtaposed cambial cells producing callus to form a functional and strong graft union. The ability to achieve this is thought to be dependent on a combination of environmental, anatomical, physiological, and genetic factors.

Genetically, grafting is most successful when the scion and rootstock are closely related – ideally, that is, scions of a mother plant grafted on her own seedling progeny. Successful grafts between species and between genera are less common. Even if a union is formed between these poorly related plants there is the likelihood that there will be tissue rejection at a later date – even many years later – which results in the breakage of the union. Often this tissue incompatability is seen as a differential in the growth rate between the rootstock and scion, with one having a larger diameter than the other.

Graft incompatibility is thought to be biochemically mediated and to depend on recognition events between juxtaposed cells through their plasmodesmatal connections. One suggestion is that it involves differences in peroxidase activity across the union, which may regulate lignification processes. A difference in the peroxidase banding patterns in both the scion and rootstock is thought to predict graft incompatibility and hence weak graft unions (Gulen *et al.*, 2002). However, despite considerable recent experimentation the mechanisms remain elusive and general principles are hard to elucidate.

Environmentally, probably the main causes of graft failure are nonoptimal temperature for cell division, loss of cell turgidity, movement at the scion/rootstock interface, and disease (Hartmann *et al.*, 2010). Consequently, grafting should be done during the growing season and with proper protection from water stress and movement. However, almost nothing is known about the importance of the preseverance irradiance, the quality of light, and the nutrient status of the severed shoot. These environmental conditions are important for the successful rooting of cuttings. Likewise, not much is known about the best pregrafting environment for rootstocks.

Physiologically, the need for vigorous growth is widely recognized. However, in temperate trees success is often greatest when dormant scions that have been held in chilled storage are grafted to rootstocks that are already in active growth. This may reflect the reduced chance of water stress in the scion, although it may be associated with changes in the gibberellin and abscisic acid content of plant tissues.

One problem that can arise with grafting is that the scion dies, whereas the rootstock sprouts. If good observations are not made regularly, it can be difficult to know whether the shoots of a grafted plant are of the selected scion clone, or of the unselected rootstock seedling. Of course, if the latter occurs the grafting exercise will be a waste of time, effort, and money.

Marcotting or Air Layering

Layering, the stimulation of roots on intact stems in contact with the ground, is a natural feature of many plants, including some trees. This has been modified as an artificial process of vegetative propagation in two main ways – stooling and air layering (or marcotting). In the former, soil mounds are built around the shoots emerging from coppiced stumps and then the rooted shoots are severed from the stump and planted. This typically captures the juvenile characteristics of the tree associated with the base of the tree trunk.

Air layering is usually applied to mature (capable of flowering and fruiting) branches within the tree crown, usually a long way from the ground (Tchoundjeu *et al.*, 2010). In this case, a ring of bark is removed to promote the accumulation of photosynthates. Then the exposed cambium is typically treated with an auxin rooting powder to promote rooting. It is then wrapped in black polythene enclosing damp compost, peat, or other rooting medium and left for some weeks or months to form roots (**Figure 1**). This treated part of the branch should be close to the main stem. Once rooted the branch is severely pruned and detached from the tree and potted in a nursery.

Typically, air layered shoots form roots on the underside of the stem, which means that when subsequently planted out the tree does not have a radially orientating root system, and hence is prone to fall over as the tree gets bigger. To avoid this it is preferable to air layer vertical shoots, such as those formed after pollarding a tree. Alternatively, if a nonvertical branch is used, it can be potted and managed as a stockplant from which to regularly harvest cuttings for subsequent repropagation.

Rigorous studies are needed to determine the best environmental or physiological conditions for successful air layering, although it is affected by branch diameter/age and by season.

Stem Cuttings

The vegetative propagation of plants by rooting stem cuttings is relatively easy in annual herbaceous species, but becomes progressively more difficult as the subject becomes larger and more long-lived. Consequently, large trees provide the nursery manager with the ultimate test of skill, knowledge, and understanding. For this reason, this section focuses on some principles developed for the propagation of tree species.

A wide range of physical facilities are available for the propagation of stem cuttings. These range from sophisticated, electronically controlled glasshouses with fogging equipment, through mist propagation benches to nonmist, polypropagators that are cheap and simple to build and use. The polypropagators are very effective and appropriate for use in remote locations without access to capital and reliable water or electricity services. All these facilities are designed to reduce the postseverance physiological stress (wilting and leaf abscission) resulting from water loss through transpiration by keeping the cuttings cool, moist, and turgid.

Figure 1 A marcott set on a vertical shoot from a decapitated branch of *Dacryodes edulis*. Courtesy of Roger Leakey.

Stem cuttings can come in many forms, but the two major groups are leafy softwood cuttings from relatively unlignified, young shoots, which are dependent of current photosynthates for rooting, and leafless hardwood cuttings from older and more lignified shoots, which depend on the mobilization of carbohydrate reserves stored within the stem tissues. The former are typically a short piece of stem – perhaps a single node with its bud and leaf and the internode immediately below it (**Figure 2**), whereas the latter is often a longer piece of stem with 2–10 nodes and internodes. It is leafless as it has already shed its leaves due to the onset of winter or a dry season. Typically, these large leafless cuttings are taken toward the end of the dormant season.

Although widely practiced for hundreds of years, much of the literature on the rooting of cuttings has been anecdotal

Figure 2 A single-node rooted cutting of *Triplochiton scleroxylon*. Courtesy of Roger Leakey.

based on the experience of individuals who have neither used standardized conditions nor adequately described their protocols. This has left a confused literature with many contradictory statements about what determines success (Leakey, 2004). It is only in the past few decades that research has examined many of the factors influencing the rooting process under standardized conditions with the intention of identifying some key principles that ensure success. Furthermore, although much research has been focused on postseverance factors, such as the use of auxin 'rooting hormones' and the physical environment of the propagation system, much less, indeed very little, research has examined the effects of the preseverance environment of shoots on their stockplants or the effects of stockplant environment. Likewise, very little was known about the interactions between pre- and postseverance factors.

This rest of this section examines five key sets of factors that play a crucial role in determining whether or not leafy cuttings rapidly form a good root system, and hence determine the success of macropropagation for the development of clonal approaches to agricultural production.

The propagation environment

The act of severing a cutting from its stockplant creates a physiological shock. To ensure good rooting, the duration and severity of this shock has to be minimized (Mesén *et al.*, 1997). Thus, the most important aspect of the propagation environment is that it minimizes the physiological stresses arising from: (1) the loss of water from the tissues due to transpiration; and (2) the loss of carbohydrate reserves due to tissue respiration. In addition, the propagation environment should encourage photosynthesis in leafy cuttings, and promote meristematic activity (mitosis and cell differentiation) in the stem. These processes are linked to the need to transport assimilates and nutrients from the leaf to the base of the stem, and water from the base of the stem to the leaf.

To minimize these stresses the basic principles are to keep the cuttings well supplied with water at the cutting base, while also maintaining the leaves in an environment with high humidity (low vapor pressure deficit (VPD)). The aerial environment in the propagation area is kept cool by shading, and the leaves themselves are cooled by the evaporation of moisture from the leaf surfaces. It is important that the level of shading does not restrict photosynthesis in the leaves (i.e., typically above 400 μmol m^{-2} s^{-1}).

Comparative studies have identified that one of the major advantages of the environment in nonmist polypropagators (**Figure 3**) is their greater uniformity in both the moisture content of the rooting medium and the VPD across the beds; resulting in overall lower air and leaf temperatures (Newton and Jones, 1993). Mist systems have lower uniformity as a result of both the temporal and spatial distribution of moisture disbursed by intermittent bursts of pressurized mist from jets typically 0.5–1.0 m apart. In addition, peaks of VPD are associated with peaks in irradiance. Species vary in their sensitivity to VPD. This is a result of differences in leaf morphology which affect stomatal conductance, and is often associated with evolutionary adaptations to the physical environment found in the natural range of the species (e.g., rain forest vs. woody savannah).

The predominant use of mist and fogging systems by research teams has resulted in few studies on the relationship between photosynthesis and the rooting process due to the difficulty of measuring gas exchange in cuttings with wet leaves. However, studies of gas exchange during propagation have been made in nonmist polypropagators and these have illustrated the importance of photosynthesis for good rooting success, speed of rooting, and the number of roots produced per cutting (Hoad and Leakey, 1994, 1996).

There is a general assumption that the successful rooting of cuttings is associated with a positive carbon balance (i.e., assimilate production > losses through respiration) and a concentration gradient within a cutting which enhances the transport of assimilates from the leaves toward the cutting base. However, little is known about the relationships between respiration losses and cutting origin, leaf area, stem length/diameter, or the rooting environment.

In addition to the aerial environment of the propagator, the environment of the rooting medium is also important. However, the choice of medium is often based on availability of the materials or personal experience. Nevertheless, studies suggest that the medium should hold the cutting firm with its leaf held above the surface of the medium. In addition to providing moisture at the cutting base the medium should allow respiration from the tissues and prevent anoxia which encourages

Figure 3 Left: Nonmist propagator with its lid open. Right: A cross-section showing the different layers of gravel and medium. The arrow marks the top of the water. Courtesy of Roger Leakey.

rotting and cutting mortality. To prevent this, the medium should have an air:water ratio that optimizes the oxygen diffusion rate vis-à-vis the needs of tissue respiration. In practice, this involves the use of variously sized particles (sand and gravel) and a water-holding medium (compost, perlite, vermiculite, peat, coir, or other organic products) alone or in various mixtures. As in the relationship between leaf morphology and the aerial environment, there is some evidence that morphological and physiological adaptations to different environments may affect the optimum porespace.

Root development and growth is generally enhanced by the cutting base being warmer (artificially enhanced by providing 'bottom heat') than the leaves. This promotes meristematic activity at the cutting base, while the leaves remain cool and free from stress. The converse differential tends to promote the growth of buds creating competition for assimilates.

Postseverance treatments

Auxin applications

The application of auxin is considered to promote rooting by stimulation of cell differentiation, the promotion of starch hydrolysis, and the attraction of sugars and nutrients to the cutting base, but a better understanding is needed of the mechanisms regulating auxin concentrations and pathways (Atangana *et al.*, 2011). Indole-3-butyric acid (IBA) is typically the most effective auxin. However, auxins are not a 'cure-all' treatment and exogenous applications of auxin do not promote rooting in cuttings that are morphologically or physiologically dysfunctional. Thus, for auxins to have their stimulatory effects the cuttings should have been taken from shoots that are preconditioned by stockplant management to be physiologically active when in the propagator, free from water and respiratory stresses, and with the capacity to mobilize stored or current assimilates.

A point of practical importance is that the stems of some species are hairy, whereas others are waxy. This affects the retention of applied auxin. In addition, uptake is affected by the cross-sectional area of the cutting base (i.e., stem diameter).

Leaf area

The rooting of softwood cuttings is typically dependent on the presence of a leaf. Studies using infrared gas analyzers to measure the rates of photosynthesis in nonmist polypropagators during the propagation process found that rooting ability was maximized in photosynthetically active cuttings. However, a large photosynthetically active leaf is also actively losing water by transpiration and can suffer water stress – hence closing its stomata or shedding its leaf. This then prevents further photosynthesis. Conversely, small-leaved cuttings with inadequate assimilate production rapidly decline in their carbohydrate (sugars and starch) content due to respiration losses and hence cannot support root development.

Successful rooting, therefore, requires an optimal leaf area which balances the positive effects of photosynthesis and the negative effects of transpiration (Leakey, 2004). The leaf area associated with this balance varies depending on the adaptations in leaf morphology of different species to different environments. Such variation is also determined by leaf age (node position) and the position of a shoot with the stockplant.

In addition to leaf area, the correct balance between photosynthesis and transpiration will also be determined by the photosynthetic efficiency of the leaf due to the light environment of the propagator (level of irradiance) and the cutting's water relations (affected by the aerial environment of the propagator and the air:water ratio of the medium). Studies of these important aspects of propagation have found a. relationship between rooting ability and the content of reflux-extracted soluble carbohydrates, which confirm the importance of assimilate production throughout the rooting process.

The determination of the optimum leaf area is, therefore, a very important aspect of developing a successful propagation protocol, especially in difficult-to-root species.

In general, rooting experiments focus on the factors enhancing rooting success. However, to learn more about the processes affecting rooting, there is much that could be learnt from paying more attention to the causes of rooting failure. For example, more information is needed about how and when cutting death can be attributed to: water and heat stress, leaf abscission, photoinhibition, negative carbon balance, etc. In addition, some cuttings neither die nor root.

Other related reasons for the failure of cuttings to root can be the death of the leaf due to microbial infection, anoxia and rotting, necrosis, bleaching, or leaf abscission. These problems can arise due to the use of old shoots with senescent or photosynthetically inactive leaves that are past their compensation point (photosynthetic activity vis-à-vis senescence); water stressed or starch filled. The most common

symptoms are leaf shedding, leaf rot, and stem rot. Gaining an understanding of these causes of cutting death and hence the failure of the propagation process can be as important as determining how to achieve good rooting.

Despite the importance of photosynthesis for the rooting of leafy softwood cuttings, there is some evidence that some species are also able to mobilize and use stored reserves of carbohydrates to contribute to the rooting process. This may reflect differences in stem anatomy and perhaps also adaptations to seasonally harsh environments.

Cutting length

The stem length of a cutting is another important variable affecting rooting success (Leakey, 2004). It is important in two ways. First, it affects the depth of insertion into the rooting medium, as well as the height of the leaf above the surface of the rooting medium; and second, it inherently affects the capacity of the cutting to root. This is something that will be investigated later. Both the depth of insertion and the height of the leaves above the medium can be important in terms of providing uniform conditions for water uptake and preventing competition between cuttings for light. It is also desirable to prevent the leaves from touching the medium and getting saturated by water droplets.

Cuttings can be cut to a constant length (these may vary in the number of nodes and leaves present), or can be cut to the length determined by a chosen number of nodes. The simplest cutting is a single-node cutting. It has one internode and generally has one leaf and one bud. In this case, the internode will generally vary in length depending on its position within the stem (**Figure 4**). As a general rule, basal internodes are shorter than more apical ones, reflecting the vigor of growth at the time the node was formed in the terminal bud. This within-stem variability will be examined later. For practical purposes it is probably best to use a constant length close to the optimum, although this may not result in the availability of greatest number of cuttings.

Figure 4 The node-to-node variation in the length of the internode and the petiole in cuttings from the top two shoots of a *T. scleroxylon* stockplant (uppermost nodes on the left). Courtesy of Roger Leakey.

Stockplant factors: Cutting origin and environment

There are two major sources of variation attributable to the stockplant, which are: (1) within-shoot factors; and (2) between-shoot factors. Both of these are subject to the stockplant environment and hence can be influenced by stockplant management.

Within-shoot factors

It has been shown earlier that single-node cuttings vary in their internode length (**Figure 4**). This variation is associated with gradients in numerous other variables which basically run from the bottom to the top of the stem in parallel with chronological age, such as: leaf size, leaf water potential, leaf carbon balance, leaf senescence, internode diameter, stem lignification, nutrient and stem carbohydrate content, and respiration (Leakey, 2004). Thus, no two cuttings are identical and, as a consequence, no two cuttings have the same rooting ability (**Figure 5**). This is because all these variables affect the physiological processes in the cutting. A number of studies have used this node by node variation as an experimental variable to examine some of the key factors affecting rooting ability. For example, a comparison of the normal gradient in cutting length with an inverse gradient showed the importance of cutting length, whereas a comparison with standard length cuttings showed the importance of cutting diameter/volume. It seems that the stem volume of the cutting determines the storage capacity of the cutting for current assimilates. In this connection, there are interactions between stem volume and leaf area. The stockplant environment and/or stockplant management also interact with node position in ways that help to elucidate the effects of different treatments. Studies of this sort have shed light on the relative importance of carbohydrates and nutrients in the rooting process.

Between-shoot factors

As plants grow and increase in size they branch and become more complex. This creates competition between shoots for assimilates and nutrients; as well as causing mutual shading between leaves. This competition is made more complex by the processes of correlative inhibition and the development of dominance between shoots, which are mediated by growth regulators as well as by the plant's environment: especially light and nutrients (Leakey, 2004).

To maintain stockplants in a good condition for easy rooting they need to be pruned back hard to leave a short stump of approximately 20 cm. So the simplest form of stockplant is that which has just been cut back once and which then sprouts from its uppermost remaining buds. A comparison of the rooting ability of these different shoots has found that cuttings from the uppermost shoot roots best and those from lower shoots root progressively less well. However, if such stockplants are cut back to different heights (say between 20 and 100 cm) then usually the taller stockplants produce more shoots. In this case, the rooting ability of cuttings from the top shoot declines with increasing height and a relationship is found between the number of shoots and the percentage of cuttings rooted (**Figure 6**). This implies that competition between the shoots reduces rooting ability and the removal of the lower shoots increases the rooting ability of cuttings from upper shoots.

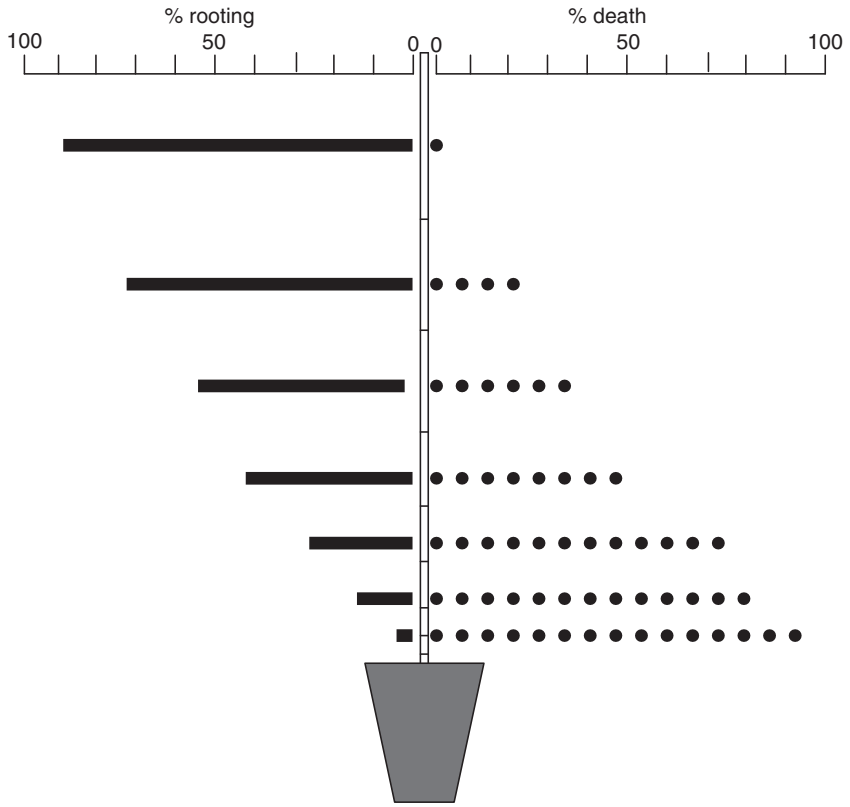

Figure 5 The gradient of variation in rooting ability within a shoot; the long uppermost cuttings root best, whereas short basal cuttings die.

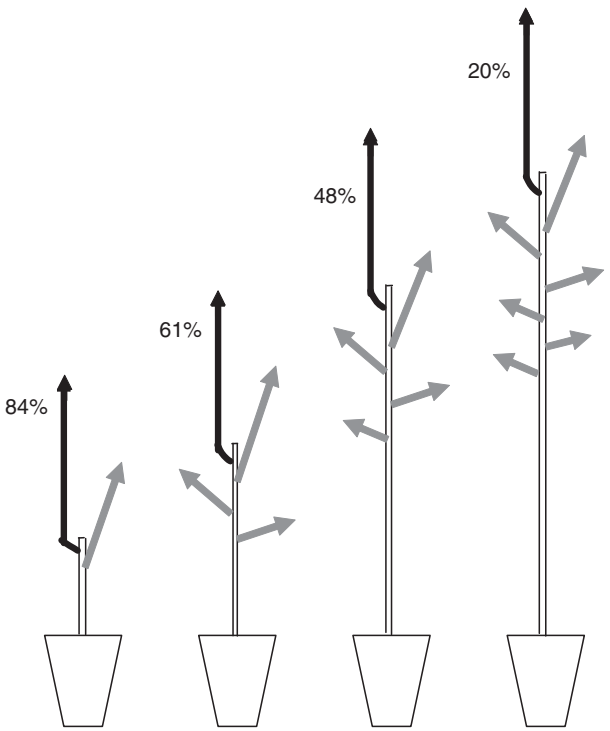

Figure 6 Effects on the rooting success of cuttings from the top shoot of stockplants pruned to different heights. Cuttings from short stockplants with few shoots root best.

Further studies to test the competition hypothesis in plants of the same height have found that other factors also seem to be involved. For example, the lower shaded shoots can root very much better than less shaded shoots, especially under conditions of high soil nitrogen. Additionally, reorienting the stockplant so that its stem is not vertical (e.g., 45° or 90° from the vertical) alters the location of vigorous growth and the fast-growing lower basal shoots become the most easily rooted. Thus, in addition to competition there are effects of shoot position and of stockplant environment.

When studies tried to elucidate these interactions between-shoot position and intershoot competition in two-shoot stockplants of the same height, it was found that basal shaded shoots had a higher rooting ability than upper shoots. However, if these basal and upper shoots were under conditions with the same light environment (irradiance) the differences between-shoot positions were eliminated (**Figure 7**). This finding led to experiments in controlled environment growth chambers to investigate the role of light (Hoad and Leakey, 1994, 1996).

Stockplant environment

As seen above, both nutrients and shade seem to affect the rooting ability of cuttings from shoots on relatively simple stockplants, but these complex preconditioning processes are poorly understood. It is clear that both the amount of light (irradiance) and the spectral quality of light (red:far-red ratio) – both features of shade – are important and independently

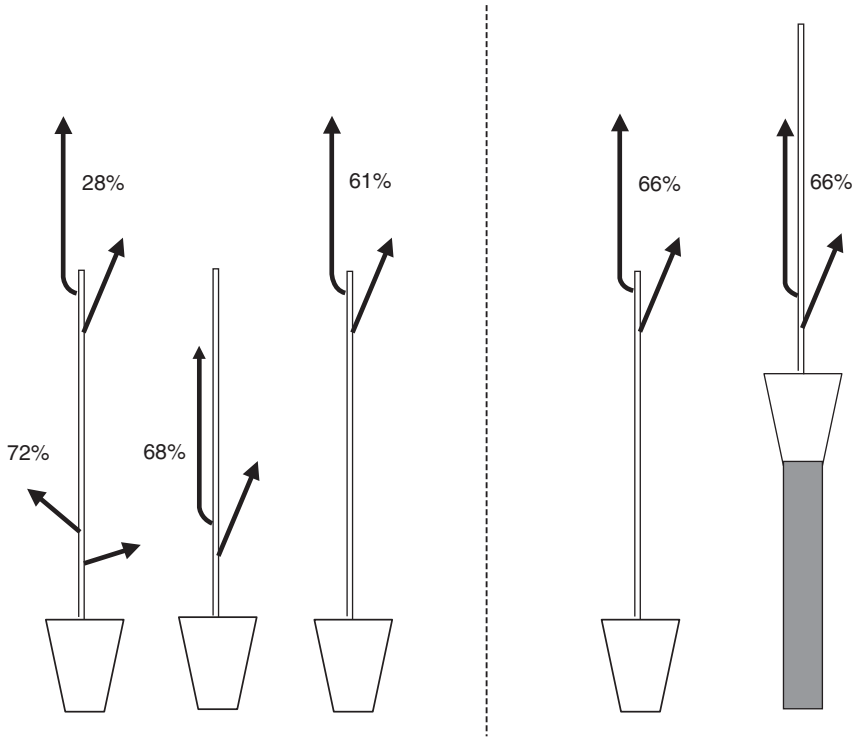

Figure 7 Effects of shoot position on the rooting success of cuttings from stockplants with apical and/or basal shoots. The effects of shade were examined by adjusting the height of the pots.

affect the rooting ability of cuttings. Shade light is also commonly associated with shoot etiolation, and hence with long internodes and with large thin leaves. These effects are then further complicated by an interaction with soil nutrients which promote shoot growth (Leakey and Storeton-West, 1992). The light/nutrient interaction affects photosynthetic processes. The most dramatic of these interactions seems to be the combination of high irradiance and low nutrients which results in short starch-filled stems, the inhibition of photosynthesis, and very poor rooting (**Figure 8**). At the other extreme, low irradiance and high nutrients is associated with active photosynthesis, low starch, and good rooting.

These preconditioning effects of irradiance, light quality, and nutrients on morphology are also associated with physiological differences in the stems and leaves of the shoot preseverance (Hoad and Leakey, 1994, 1996). Physiologically, shade reduces the tendency of the top shoot to dominate and reduce the growth of other shoots (i.e., promotes codominance), lowers the rates of preseverance net photosynthesis, lowers leaf chlorophyll concentration, but stimulates higher rates of net photosynthesis per unit of chlorophyll. Preseverance conditioning thus actively promotes postseverance photosynthesis during the rooting process. Such shoots are therefore said to be physiological 'young,' whereas shoots with low vigor and inhibited photosynthesis are physiologically 'old.'

A mechanistic model of carbohydrate dynamics during the rooting process can be used to gain further insights into the rooting process (Dick and Dewar, 1992) and to define key principles for the development of robust rooting protocols.

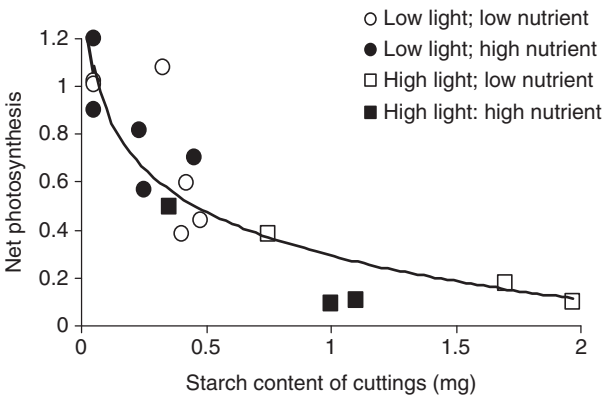

Figure 8 The effects of growing stockplants at two levels of light (low and high irradiance) and two levels of nutrients (low and high). This affects the rates of photosynthesis and the starch content of cuttings. Starch-filled cuttings with low rates of photosynthesis rooted very poorly. Modified from Leakey, R.R.B., Storeton-West, R., 1992. The rooting ability of *Triplochiton scleroxylon* K. Schum. cuttings: The interactions between stockplant irradiance, light quality and nutrients. Forest Ecology and Management 49, 133–150.

Stockplant Management

The major importance of all of the above morphological and physiological stockplant factors makes it clear that stockplant management (a combination of regular pruning, fertilizer use, and light management) should be a key component of any macropropagation protocol. To retain physiological youth,

Table 3 The importance of stockplant management for successful vegetative propagation. Note the lack of relationship between rooting percentage and the numbers of plants established, which reflects the understanding of the importance of stockplant management (which shoots to use and the role of stockplant environment)

	Standard hedged stockplant No knowledge of stockplant management	*Standard hedged stockplant Knowledge that rooting is best from upper shoots*	*Preconditioned (far-red light and fertilizers) hedged stockplant Knowledge that preconditioning improves physiological activity and rooting capacity*
No. of cuttings harvested	31	16	45
No. of cuttings rooted	16	16	40
Percentage of cuttings rooted	52	100	89
No. of plants established	16	16	40

stockplants are often managed as hedges. Using nitrogen-fixing tree/shrub species to shade these hedges then maximizes the rooting success by provision of desirable light and soil nutrient environments.

One of the issues that has created much of the confusion in the scientific literature of vegetative propagation is the very common (even ubiquitous) use of percentage of rooting as the measure of success. Rooting percentage is, however, affected by the standards of stockplant management and use of the best shoots (the shoots with optimal morphology and highest physiological activity; **Table 3**). Contradictory results arise in the literature when authors do not provide the relevant information in the description of their experimental protocols.

Phase Change

The vegetative propagation literature has numerous references to what is called 'Phase Change' or ontogenetic aging. This literature basically attributes the loss of rooting ability as perennial plants age and get larger to their gradual transition from the juvenile phase of vegetative growth to a phase of sexual maturity. The propagation of mature tissues is one of the major constraints to many tree improvement programs focusing on cultivar development through macropropagation. This loss of rooting ability with increasing size and structural complexity is perhaps not surprising given the already mentioned effects of stockplant factors in even small and simple stockplants. Nevertheless, the importance of phase change vis-à-vis rooting ability is an unresolved aspect of vegetative propagation (Leakey, 2004).

The phase change hypothesis assumes that plants (and trees in particular) gradually progress from juvenility (sexually immature and easy to root) to maturity (sexually mature and capable of flowering and fruiting associated with low rooting ability) over time. In trees, maturity may not be achieved for 3–20 years. It is generally recognized that the best way to return a tree to the juvenile state is to cut it down and to allow coppice shoots to grow from the stump. These coppice shoots are young and vigorous and cuttings from them can usually be rooted easily. Studies have suggested, however, that there is a decline in rooting ability with the increasing diameter of the stump. It is not known whether this is due to some aspect of the aging process or to stockplant factors like those mentioned for seedlings above. For example, large stumps generally produce more shoots than smaller stumps. This loss of rooting ability could, therefore, be due to increased intershoot competition.

There are some inconsistencies between the concept of 'phase change' and observation. Originally the hypothesis was based on the work on ivy (*Hedera helix*) which has various leaf shapes. It was assumed that the normal palmate leaves of climbing ivy vines were characteristic of the juvenile easy-rooting phase, whereas the ovate leaves of flowering shoots were assumed to be characteristic of the difficult-to-root mature phase. Observation of large ivy plants suggests a different interpretation as palmate leaves can be seen to be associated with main stems (the climbing vine), whereas ovate leaves are associated with free-standing branches on which flowers are formed. The association of flowering with branches is common in many woody plants, and it is not unusual for branches and main stems to differ in the arrangement of their leaves and buds. Certainly, in ivy, it is common to see old and large vines climbing a cliff or dead tree with palmate leaves tens of meters above the ground, and flowering branches with ovate leaves all the way up the vine.

A second way in which the hypothesis is not supported is the evidence that ontogenetically mature plants (with the capacity to flower and form fruits) propagated by cuttings, grafts, or marcotts can be easily repropagated by cuttings when they are used as small managed stockplants. Although often plagiotropic, such stockplants have the vigor of juvenile seedlings and coppice shoots. This suggests that the poor rooting ability of 'mature' shoots can be attributed to 'physiological aging' rather than to 'ontogenetic aging.' In other words, the difficulty in rooting crown shoots in large mature trees is due to a severe case of the combination of undesirable morphological and physiological factors resulting from within and between stockplant factors and their interaction with the stockplant environment (Dick and Leakey, 2006). A start has been made to examine this experimentally within the crown of mature trees (Pauku *et al.*, 2010).

Genetic Variation in Rooting Ability

Early in this article, it was shown that there are genetic differences in the ease of propagation between species and even between provenances and clones within species. In severe cases, this has led to the conclusion that some species are 'impossible to root.' It has also been seen that species vary in

Table 4 The analogy between athletic ability and rooting ability in the vegetative propagation of tree stem cuttings

Sporting ability	*Rooting ability*
Young	Juvenile
Physiologically fit – lean, well-prepared, strong	Physiologically young – high rates of photosynthesis – long internodes, large leaf area, chronologically young node position
Genetic morphology – muscles, body build, etc.	Genetic morphology – stem and leaf anatomy
Preparation in gym – physiologically fit and full of energy	Preconditioning by stockplant management – physiologically active
Highly competitive and ready for action	Preconditioned to contain low starch–high soluble sugars and free from competing shoots
Use of performance-enhancing drugs	Use of auxins as rooting hormone
Stress-free Olympic village	Stress-free propagation environment
Different sports – refine training regime	Different species – refine propagation regime

Source: Modified from Leakey, R.R.B., 2012. Living with the Trees of Life – Towards the Transformation of Tropical Agriculture. Wallingford: CAB International, 200 pp.

the leaf and stem morphology, and in their adaptations and responses to environmental factors. There is now good evidence that species previously thought to be 'impossible to root' can now be preconditioned to be easier to root by good stockplant management based on an understanding of the morphological and physiological factors affecting rooting ability. Thus, the apparent genetic differences in rooting ability can instead be attributed to genetic differences in the growth and development of shoots.

The concept that inherent genetic differences in rooting ability are not critically important is also supported by the use of stepwise regression in the analysis of experimental data from rooting studies. Such analysis commonly finds that the factors explaining much of the variance are cutting length, leaf abscission, leaf area, etc., rather than clone or provenance (Dick *et al.*, 1999).

Contrary to the above, some studies to detect quantitative trait loci affecting vegetative propagation have, however, reported that phenotypic variation has a meaningful genetic component.

Conclusion

There are many facets to developing a robust approach to macropropagating plants, especially by the rooting of stem cuttings. Over the past 15–20 years much progress has been made to gain a good understanding of the numerous interacting factors (stockplant environment × stockplant management × topophytic variables × node position × nursery management × postseverance treatments × propagation environment) by studying them in tree species. This understanding now provides some general principles that can be applied to the propagation of new species, and especially those considered to be difficult to propagate.

Leakey (2012) has likened many of the factors that determine the success of propagation by stem cuttings to those that determine the success of an athlete competing in the Olympic Games (**Table 4**). This analogy has been found to help people to understand the key principles.

The greatest challenge remaining is to improve the design and reporting of experiments so that the quality of the literature is improved by researchers adequately describing the material they used, as well as the pre- and postseverance environments. This should remove the contradictory results in the literature created by people not using comparable material in terms of the physiology and morphology of the tissues used. There is then a need for more extensive studies of the importance of stockplant management and the stockplant environment across a wider range of species.

Glossary

Disease The continuous abnormal functioning of an organism; a disruption in the health of the organism.
Effectors Pathogen proteins and small molecules that alter host–cell structure and function.
Effector-triggered immunity Direct or indirect recognition of pathogen effectors by plant resistance (R) proteins that leads to the activation of plant defense responses.
Evolutionary arms race Evolutionary struggle between competing sets of coevolving genes that develop adaptations and counteradaptations against each other.
PAMP-triggered immunity First active defense response of plants, also referred to as activation of basal defenses, after perception of PAMPs by plant PRRs.
Pathogen A disease-producing organism or biotic agent.
Pathogen-associated molecular patterns Highly conserved molecules associated with groups of microbes that are recognized by pattern recognition receptors (PRRs) on plant cell surfaces to activate the innate immune system.
Plant immunity The inherent or induced capacity of plants to withstand or ward off biological attack by pathogens.

Plants Get Sick Too!

The earth accommodates a staggering number of microbes, estimated to be as high as 10^{30} (Kallmeyer *et al.*, 2012). Among these microbes are as many as 5.1 million different species of fungi (Blackwell, 2011), more than 8000 of which cause disease on plants. Given the huge variety of plant pathogenic microorganisms, which also include viruses, bacteria, oomycetes, and nematodes, why are there so few diseased plants in nature? The reasons are many. Most microbes do not have the capacity to cause disease in plants, and those that do range from very efficient to very weak pathogens. Some microbes are even beneficial to plants, facilitating their growth in nutrient-limiting or adverse environments. Even closely related plants may vary greatly in their exposure or susceptibility to pathogens, ranging from highly susceptible to completely immune (resistant). Furthermore, environmental conditions including temperature, humidity, and availability of nutrients can influence whether the plant–pathogen interactions lead to disease or resistance. The interactions of susceptible host, virulent pathogen, and conducive environment can be conceptualized as a disease triangle (Figure 1).

Agriculturists who are interested in producing healthy crops frequently focus on the plant side of the arms race, determining which adaptations make the plant resistant to disease. However, given the complicated relationship between pathogen virulence and plant immunity, the most effective approach to designing a successful disease control strategy is one that considers both the partners. This article explores attributes of plant pathogenic microbes that enable them to access host nutrients and cause disease. Mechanisms by which the plant resists invasion by pathogens, and how the intimate interactions between microbes and plants have driven their coevolution are also discussed. Finally, how knowledge of these interactions influences disease control strategies in the field is explored. Although many common themes are found among the interactions between pathogens and plants, there is also huge diversity; thus, examples used are meant to provide context to this discussion, and are not meant to be comprehensive. Furthermore, given the breadth of the topic and limited space, we rely on citation of excellent reviews, where available, and provide primary references for recent examples.

A Conceptual Basis for the Evolution of Plant–Microbe Interactions

Plant pathogens form intimate relationships with plants to gain access to host resources needed to survive, grow, and reproduce. This process, which involves infection, colonization, and pathogen reproduction, is called pathogenesis. To cause disease, plant pathogenic microbes must (1) find and

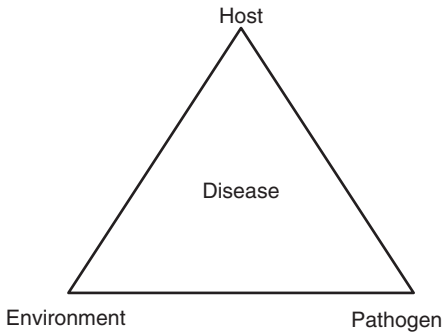

Figure 1 The plant disease triangle shows the three components necessary for disease to occur: (1) the pathogenic microbe must be virulent on a particular species and cultivar of plant; (2) the plant host must be susceptible to a particular strain/isolate/biotype of a pathogen; and (3) environmental conditions including temperature, humidity, and availability of nutrients must be suitable for the interactions that lead to disease. If a pathogen requires an insect vector for dissemination or inoculation then a fourth dimension is added (a plant disease pyramid).

 doi:10.1016/B978-0-444-52512-3.00165-0

gain access to the host plant; (2) avoid, suppress, or overcome the plant's resistance repertoire; and (3) coerce the plant to provide nutrients or replication machinery to enable growth and multiplication. However, to avoid disease, the plant must (1) recognize the presence of potential pathogens and (2) mount a defense response that has sufficient strength to restrict pathogenic attack without being too detrimental to the plant's own physiology. The variation in virulence on the part of the pathogen and susceptibility or resistance on the part of the plant are the result of a coevolutionary arms race (Anderson *et al.*, 2010). Increased virulence of a pathogen places a strong selective pressure on the plant host to increase resistance; in response, the pathogen is under selective pressure to overcome resistance. A simple 'zigzag model' (**Figure 2**) was proposed to illustrate our current understanding of plant–pathogen interactions in an evolutionary context (Jones and Dangl, 2006). In this article, a step-by-step walk will be taken through the zigzag model to frame the discussion of the processes in pathogen–plant interactions that culminate in disease or resistance.

How do Pathogens Find and Enter the Plant?

For a microbe to cause disease, it needs to come into direct contact with its host plant, and often with a specific host plant tissue. Microbes are passively distributed from plant to plant by wind, splashing rains, or insect vectors (**Figure 3**). However, nonpathogenic microbes, once deposited, do not have the capacity to find wounds or natural openings on the plant surface, or to penetrate preformed surface barriers such as a waxy cuticle and thick cell walls. Pathogens, however, have evolved diverse mechanisms to find and enter plants to establish the disease.

Once they reach the host plant, a pathogenic microbe may land on the part of the plant suitable for infection, called the infection court. In other cases, pathogens need to expend energy to move or grow toward the infection court. Elegant work in the 1970s–1980s demonstrated that mycelia of some fungi exhibits directional growth toward the infection court of their host, in this case the stomata (for a review, see Tucker and Talbot, 2001; Mendgen *et al.*, 1996). For example, mycelial growth of *Uromyces appendiculatus*, the causal agent of bean rust, is oriented perpendicular to the ridges surrounding the stomata, a process known as thigmotropism (**Figure 4**) (Hoch *et al.*, 1987). Stomatal ridges of a height specific to bean signal the fungus to form specialized infection structures that penetrate the stomatal opening, a process called thigmodifferentiation.

Some pathogens orient themselves toward an infection court by sensing electrical fields (electrotaxis) or chemical signals (chemotaxis). Swimming spores of the oomycete *Pythium aphanidermatum*, which infects roots through wounds, are attracted to the negative charges associated with wounds along the root surface; *Phytophthora palmivora* zoospores, which can directly penetrate undamaged roots, are attracted to positive charges (van West, 2002). Access to wounds or natural openings by plant pathogenic bacteria such as *Agrobacterium* spp. *tumefaciens* (crown gall of most dicots), *Erwinia amylovora* (fireblight of apple and pear), *Pseudomonas syringae* pv. *glycinea* (bacterial blight of soybean), and *Pseudomonas lachrymans* (angular leaf spot of cucumber) is facilitated by chemotaxis toward simple plant chemicals such as sugars or phenolics.

Once the pathogen reaches the infection court, it needs to enter the plant (**Figure 3**). Unless the pathogen can enter the plant through indirect penetration of wounds or natural openings or is vectored by an insect, it must create an opening to enter the plant through direct penetration. Plant surfaces are barriers to pathogens, and surface structure varies widely among plants and among tissues on the same plant. Woody stems present a very different set of barriers to pathogens than leaves or flowers do. A typical leaf surface presents a tough outer cuticle that is composed of an insoluble polyester, cutin, embedded in a complex mixture of waxes. The thickness of the cuticle varies among species, organs, developmental stages, and environmental conditions. Many pathogens have evolved elaborate mechanisms for breaking through this barrier, which are usually only employed during the penetration phase of the life cycle. Fungi can penetrate the cuticle by chemical or enzymatic degradation or by force. *Magnaporthe oryzae*, a fungal pathogen causing rice blast disease, uses both the mechanisms. After the fungal spores germinate on the plant surface, the mycelia form specialized penetration structures called appressoria. Each appressorium is held in place on the leaf surface by a fungal-produced mucilage that is so sticky that it sticks to Teflon (Hamer *et al.*, 1988). The appressoria secrete cutinase, an enzyme that degrades and weakens the cuticle (Skamnioti and Gurr, 2007). Then, after building up enormous levels of turgor pressure, the appressorium forces an appendage called the penetration peg through the cuticle and the cell wall (Howard and Valent, 1996).

PAMP-Triggered Immunity: The First Line of Active Defense

For those microbes that get beyond the preformed structural barriers, the zigzag model proposes that the first line of active plant defense is PAMP-triggered immunity (PTI). PTI, the set of general defense responses of plants to diverse microbes, is a process by which plants actively recognize 'nonself' from 'self' via surface receptor molecules called pattern recognition receptors (PRRs). PRRs are membrane-spanning proteins with extracellular receptor domains. The receptor domains of PRRs recognize highly conserved pathogen molecules called pathogen-associated molecular patterns (PAMPs, also called microbe-associated molecular patterns or MAMPs) activating a signal transduction cascade that culminates in the induction of a suite of defense responses. PTI-associated defenses may include the production of reactive oxygen species, increases in intracellular calcium concentration, callose deposition in cell wall, activation of mitogen-activated protein kinases (MAPKs), production of antimicrobial compounds called phytoalexins, and a complex transcriptional response (Schwessinger and Zipfel, 2008). Together, these PTI-activated defense responses are the chief means by which microbes that get past plant structural barriers.

Plant-derived peptides or cell wall fragments that are released by pathogen degradation, called damage-associated molecular patterns (DAMPs), can also be recognized by PRR and activate signaling of PTI (reviewed by Monaghan and

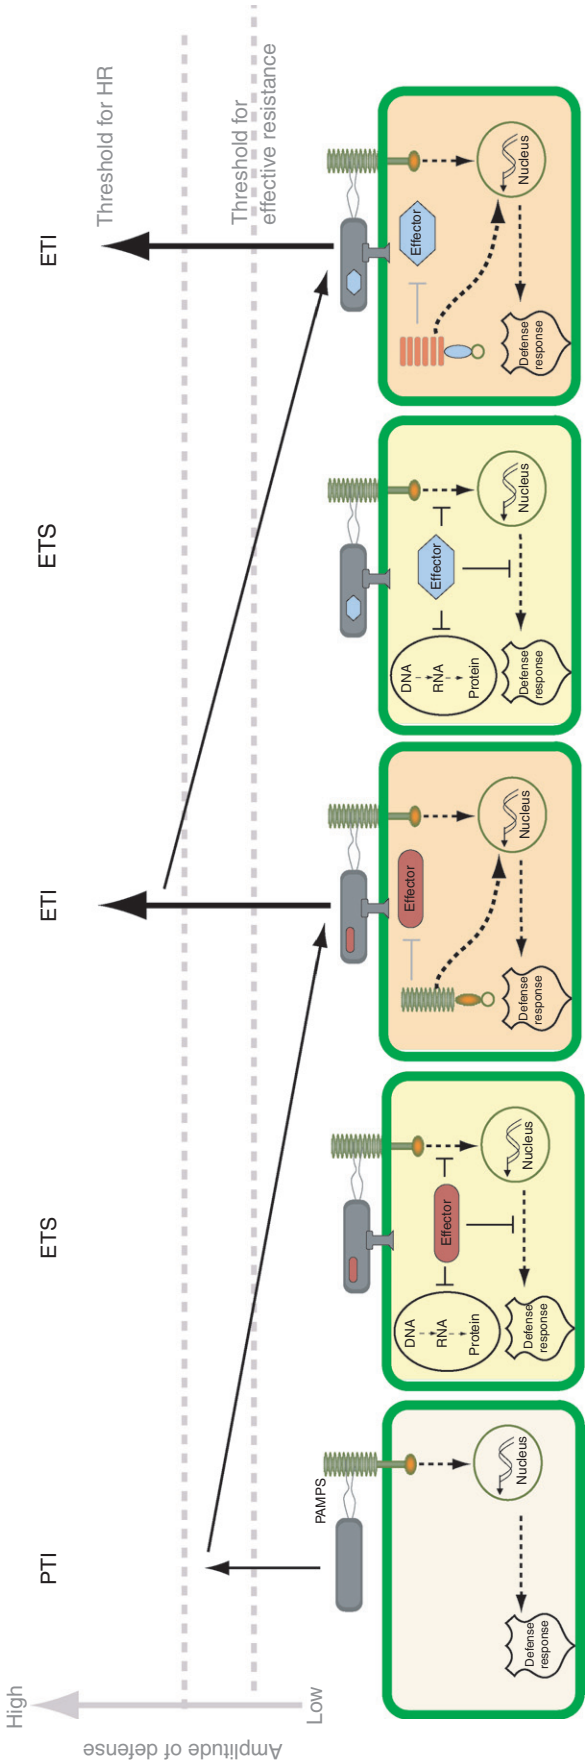

Figure 2 The zigzag model to illustrate the coevolution of the plant immune system and pathogen virulence effectors. Plants detect pathogen-associated molecular patterns (PAMPs) via pattern recognition receptors (PRRs) to trigger PAMP-triggered immunity (PTI). Pathogens evolve effectors that interfere with PTI or other host processes to result in effector-triggered susceptibility (ETS). In response, plants evolved NB-LRR proteins to detect effectors and to activate effector-triggered immunity (ETI). ETI has a higher amplitude (stronger and longer lasting response) than the PTI. Within the pathogen populations, pathogen isolates are selected that have lost the recognized effector, leading to suppression of ETI and restored ETS. Finally, new plant NB-LRR alleles are selected that can recognize a new effector, restoring ETI. Hypersensitive response (HR). Image drawn by Samuel Vazquez III adapted from Jones, J.D., Dangl, J.L., 2006. The plant immune system. Nature 444 (7117), 323–329, and Chisholm, S.T., Coaker, G., Day, B., Staskawicz, B.J., 2006. Host-microbe interactions: Shaping the evolution of the plant immune response. Cell 124 (4), 803–814.

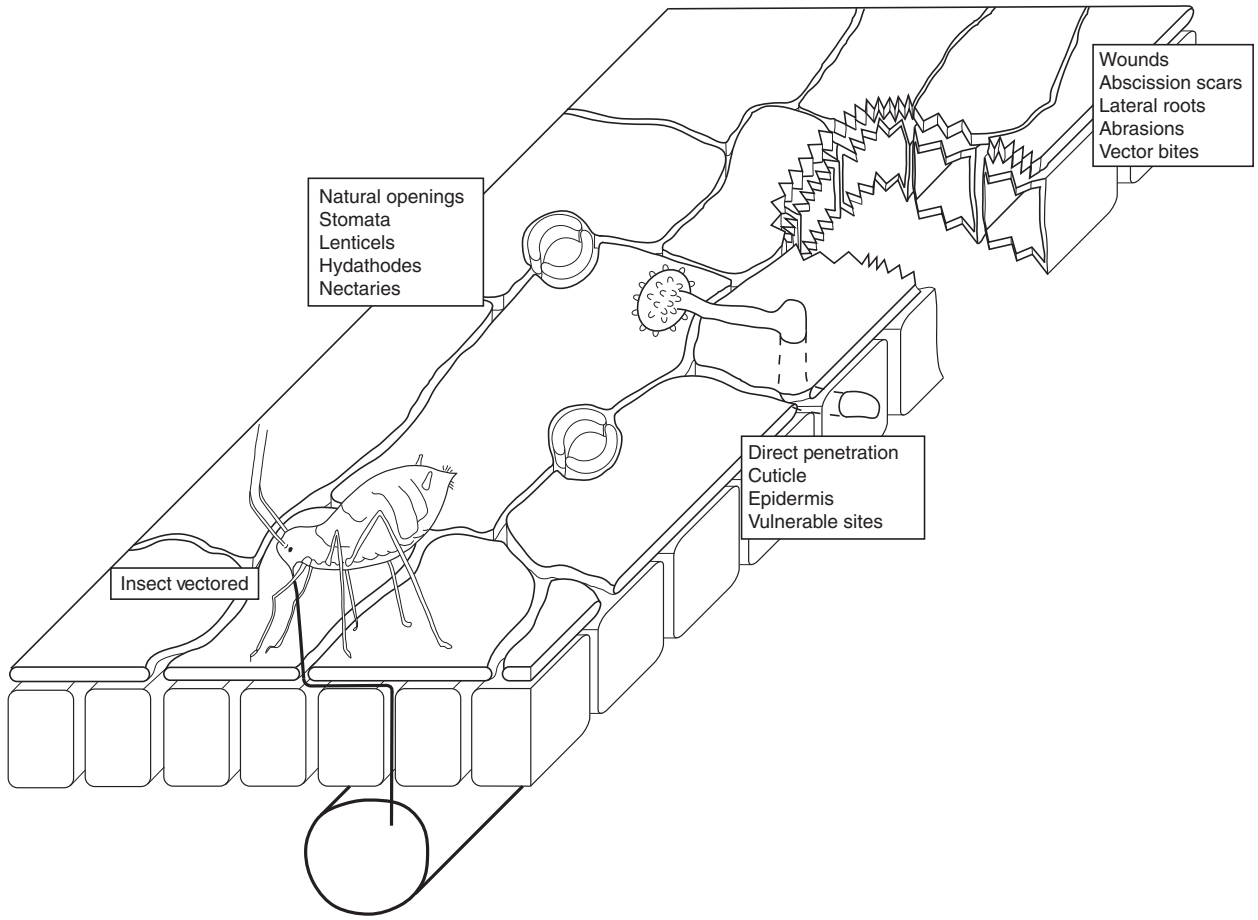

Figure 3 Methods of penetration and invasion by plant pathogens. Pathogens can enter through wounds (e.g., Tobacco Mosaic Virus, *Agrobacterium* spp. *tumefaciens*, and soft rot fungi) or natural openings such as stomata (rust fungi and *Pseudomonas syringae*), lenticels (*Pectobacterium carotovorum*), or hydathodes (*Xanthomonas oryzae* pv. *oryzae*). Fungi that can directly penetrate are powdery mildews, downy mildews, or *Magnaporthe oryzae*. Pathogens that are delivered by insect vectors include *Xylella fastidiosa*, Cauliflower Mosaic Virus. Image drawn by Samuel Vazquez III and Tony Campillo.

Zipfel, 2012). In one example, plants produce proteins that inhibit the activity of fungal-produced cell wall degrading enzymes called endopolygalacturonases. The plant-produced inhibitors reduce the activity of the endopolygalacturonases, leading to the accumulation of long-chain oligogalacturonides that function as DAMPs and trigger PTI (D'Ovidio *et al.*, 2004).

PAMPs tend to be highly conserved, essential components of the pathogen, so any mutation that affects their function is likely to be detrimental to the pathogen. Some PAMPS conserved among multiple microbes can be recognized by a single plant receptor, allowing a high degree of efficiency in the deployment of plant resources. For these reasons, PAMP receptors can confer resistance that is stable and broad spectrum, or effective against diverse pathogens. Not surprisingly, pathogens have evolved adaptations to overcome PTI. This may occur through the rare evolution of a PAMP to avoid recognition, or, more commonly, through the production of virulence effectors that enable the pathogen to overcome or avoid PTI and cause disease (reviewed by Pel and Pieterse 2013).

Effector-Triggered Susceptibility: The Pathogen Retaliates

Bacteria, fungi, oomycetes, and nematodes produce a suite of virulence effectors that are broadly defined as pathogen-produced proteins or metabolites that directly interact with the host and enhance virulence (Hogenhout *et al.*, 2009). Effectors are used by the pathogen to access nutrients, adversely affect host physiology, or to block PTI; the zigzag model describes this as effector-triggered susceptibility (ETS) (Jones and Dangl, 2006).

Collectively, effectors contribute to diverse pathogen lifestyles ranging from necrotrophy to biotrophy. Necrotrophic pathogens kill plant cells by producing effectors such as toxins or tissue-degrading enzymes; these effectors induce cell necrosis and cause leakage of nutrients that are used as substrates by the pathogen. Necrotrophic pathogens include the bacterial soft rot pathogen *Pectobacterium carotovorum* subsp. *carotovorum*, the fungal gray mold pathogen, *Botrytis cinerea*, and the oomycete root rot pathogen *P. aphanidermatum*. Biotrophic pathogens require living plant cells, and use complex

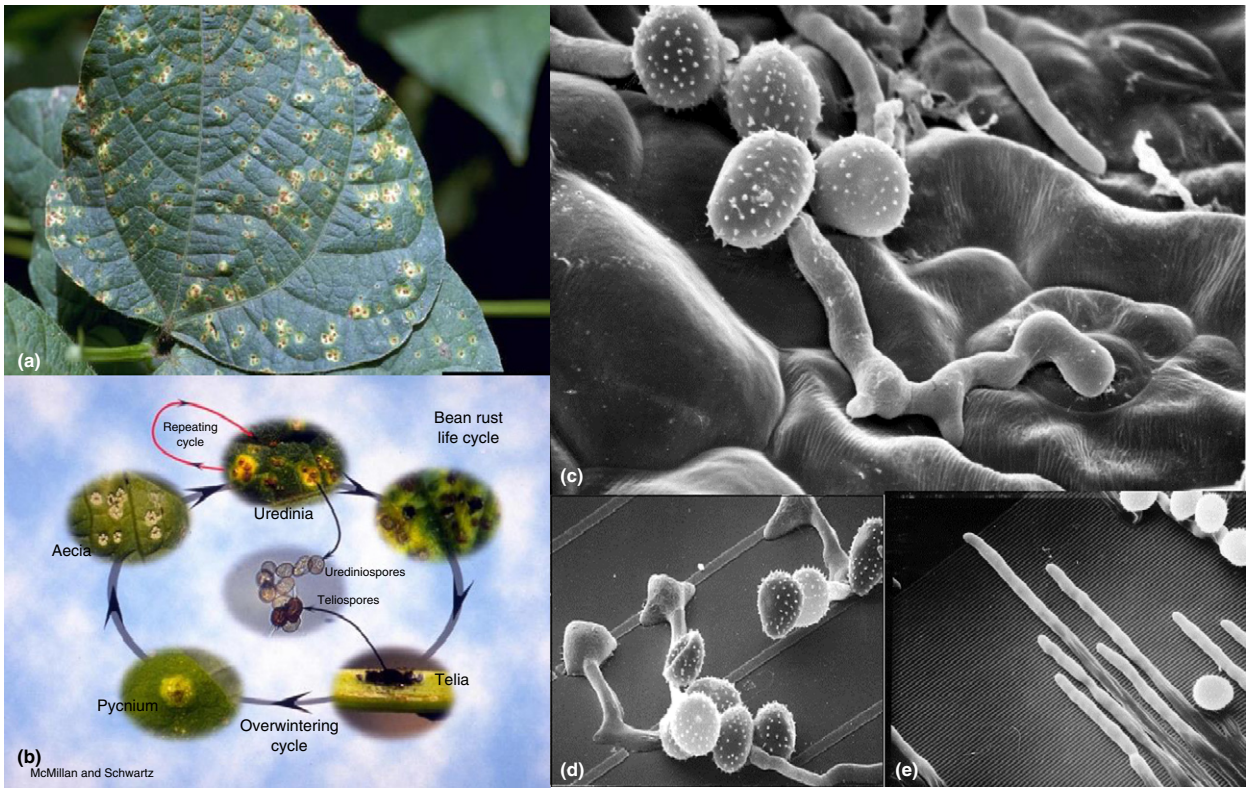

Figure 4 *Uromyces appendiculatus*, the bean rust pathogen, exhibits growth and differentiation directed by contact stimuli (thigmotropism and thigmodifferentiation, respectively). (a) Symptoms of bean rust. (b) Life cycle of *U. appendiculatus* on bean (*Phaseolus vulgaris*) showing the stage at which urediniospores are important. (c) Urediniospore germlings on the leaf surface of a bean leaf. The germling grew oriented to the stomata, and then differentiated into an appressorium (infection structure) over the stomate. Signaling for growth orientation and cell differentiation by surface topography in uromyces. Science 235 (4796), 1659–1662; and (e) photo provided by Harvey Hoch.

mechanisms to derive nutrients from the live host. Biotrophs include fungi that cause powdery mildew (*Blumeria graminis* f. sp. *hordei*) and downy mildew (*Plasmopara viticola*), and *Xanthomonas oryzae* pv. *oryzae*, the bacterial blight pathogen of rice. Hemibiotrophic pathogens exhibit both biotrophic and necrotrophic life stages, keeping the plant cells alive in the early stages of infection, and killing them at later stages. These include the rice blast pathogen *M. oryzae* and the anthracnose pathogen *Colletotrichum lindemuthianum*. Although these three broad infection mechanisms (biotrophy, necrotrophy, and hemibiotrophy) provide a useful way to classify pathogens, there is no consistent agreement on what common features are relevant to support inclusion of a pathogen within a group. For example, *Phytophthora infestans*, the important oomycete pathogen that causes late blight of potato, has been classified as by various authors as a biotroph, hemibiotroph, and even a necrotroph (Oliver and Ipcho, 2004).

How do Pathogens Deliver Virulence Effectors?

Pathogens may secrete effectors into the plant apoplast (the space outside of the plasma membrane) or directly into the plant cell. Although effector secretion is a common strategy among bacteria, fungi, and nematodes, different pathogens have evolved diverse and elaborate secretion mechanisms. Multiple effectors are delivered by one secretion system, and mutations in secretion systems that block effector transfer can severely reduce or eliminate pathogenicity.

To get outside of a gram-negative bacterial cell, an effector must cross the inner plasma membrane, the periplasmic space, and the outer lipopolysaccharide membrane. Plant pathogenic bacteria have evolved at least seven types of secretion systems to accomplish this, most of which have structural and functional counterparts among bacteria pathogenic to plants, humans, and animals (Tseng *et al.*, 2009). Secretion systems vary widely in their structural complexity, but are grouped as either one-step systems, which move proteins directly through the bacterial cell envelope (type I, III, IV, and VI systems), or two-step systems, which deliver the protein first across the plasma membrane to the periplasm and then, in a second step, across the outer membrane (type III, IV, and VI) (for a review, see Records, 2011). The simplest of these is the type I secretion system (T1SS), which spans the inner membrane, periplasmic space, and the outer membrane, and transports proteins from the bacterial cytosol directly to the outside of the bacterium. Bacteria that cause soft rot diseases use this system to deliver proteases and lipases to the apoplast of plant cells.

Type III, IV, and VI pathways have complex structures that move effectors across the bacterial envelope and can deliver the effectors directly into the host plant cytoplasm. Type IV (TT4S) pathway is notable because it is the only pathway described so far to transport both protein and nucleic acid substrates; *A. tumefaciens* uses the TT4S to deliver plant-transforming DNA, called T-DNA (transferred DNA), along with proteins into the host cytoplasm.

Type III (T3SS) pathway is structurally complex, with more than 25 proteins, and has evolutionary similarities to bacterial flagella. This system delivers effectors from the bacterial cytoplasm directly to the host plant cytoplasm using a syringe-like structure that crosses the plant cell wall. Once at the plant membrane, secreted proteins form a pore in the host membrane enabling translocation of the effector proteins into the host cell (Galan and Wolf-Watz, 2006). On the basis of analyses of sequenced genomes and subsequent functional analyses, plant pathogenic bacteria in the species of *Pseudomonas* and *Ralstonia* secrete large numbers of T3SS effectors, in some cases, more than 40. The T3SS is essential for these pathogens to cause disease.

Large numbers of proteins are secreted from bacteria via the two-step type II (T2SS) and V (T5SS) secretion systems. In these systems, the first step of protein transfer requires an amino terminal signal peptide, which is removed as the protein crosses from the bacterial cytoplasm to the periplasmic space. The effector is then transported through the outer membrane by a second complex secreton structure. Many plant cell-wall degrading enzymes (CWDEs), such as pectin lyases, polygalacturonases, and cellulases, are secreted from *Xanthomonas* and *Erwinia*-type pathogens through the T2SS pathway. *Dickeya dadantii* (*Erwinia chrysanthemii*) secretes adhesins via the T5SS pathway.

For biotrophic and hemibiotrophic fungi and oomycetes, the process of delivering effectors is less well understood. Effectors secreted to the extracellular environment are likely transported by the eukaryotic (type II) secretory pathway, a process involving exocytosis of Golgi-derived secretory vesicles. Effectors moving through this pathway carry a canonical N-terminal type II secretion signal, allowing sequence-based identification of putative effectors that function in the apoplast. The hemibiotrophic fungal rice blast pathogen *M. oryzae* delivers apoplastic effectors using type II Golgi-dependent secretory pathway (Giraldo *et al.*, 2013).

For most fungi and oomycete pathogens, the pathway for effector transfer into the plant cell cytoplasm is just becoming known. The hyphae typically differentiate into a haustorium after penetration of the host cell. As the haustorium develops, a specialized interface forms around it; this interface consists of the plasma membranes of the pathogen and the host separated by a modified pathogen cell wall. The interface allows for a two-way movement; nutrients move from the host cell to the pathogen, and effectors are delivered from the pathogen to the host. Secretion and delivery of effectors from these haustorium-forming pathogens requires N-terminal motifs (RxLR) (Tyler *et al.*, 2013). It is believed that RxLR effectors move into the host cell independent of specialized structures from the pathogens, and possibly by exploiting the plant endocytic pathway (for a review, see Panstruga and Dodds, 2009). Not all fungi use haustoria, however; *M. oryzae* effectors targeted to the host cytoplasm are delivered from invasive hyphae (the hyphae that invade inside the plant cells) into host cells via a novel plant membrane-rich structure (Giraldo *et al.*, 2013).

Nematodes deliver effector proteins into plant cells through a stylet that pierces the host cell wall. Fluids from glands that contain effectors are then secreted into the host cytoplasm through an orifice at the tip of the stylet (reviewed by Haegeman *et al.*, 2012; Torto-Alalibo *et al.*, 2009).

Effectors that are Delivered to the Plant Apoplast

Effectors that are delivered to the apoplast were the focus of early studies of host–pathogen interactions because they could often be isolated from microbes grown *in vitro*. Apoplastic effectors, including CWDEs, toxins, hormones, and cysteine-rich peptides, are considered more important for necrotrophic pathogens than for biotrophic or hemibiotrophic pathogens. CWDEs facilitate penetration of plant tissues and release nutrients from the wall polymers. Bacteria that cause soft rot diseases produce a wide range of CWDEs, including pectinases, cellulases, proteases, and xylanases. Mutagenesis studies determined the relative contribution of CWDE-encoding genes for disease, showing that pectinase genes are especially important for tissue maceration (Beaulieu *et al.*, 1993; Walton, 1994). An analysis of the mutants revealed that producing a combination of different enzyme activities allows pathogens to efficiently degrade cell walls and feed on the byproducts. Some pathogens produce multiple CWDEs with the same type of activity; *D. dadantii* produce up to nine different endopectate lyase genes that vary in activity level, optimum pH, substrate preference, and length of product. The evolution and retention of multiple CWDEs provides the pathogen with flexibility to attack different host plants under diverse conditions, such as when the pH of the tissues being degraded changes during the infection process. The redundancy of these enzymes and the genes encoding them may also be important for the survival of the pathogen as a saprophyte outside of the host plant.

In addition to making use of redundancy in CWDEs, necrotrophic pathogens usually rely on the collective contribution of different types of effectors to promote plant cell death and nutrient acquisition. For example, the arsenal of *B. cinerea*, the causal agent of gray mold, includes both CWDEs and toxic low molecular weight metabolites (Choquer *et al.*, 2007). Many fungal and oomycete pathogens secrete small, cysteine-rich proteins that protect the pathogen by inhibiting the activity of plant-produced hydrolytic enzymes (proteases, glucanases, and chitinases). Avr2, an effector produced by the tomato pathogen *Cladosporium fulvum*, inhibits the activity of tomato apoplastic cysteine proteases. *P. infestans* secretes a suite of protein inhibitors of plant cysteine proteases, subtilisin-like serine proteases, and an endo-β-1,3 glucanase.

Phytotoxins, microbial products that are poisonous to plants, are produced by many necrotrophic bacteria and fungi resulting in chlorosis and necrosis of the affected host tissues. Phytotoxins are grouped into host-selective toxins (HSTs) and general toxins. HSTs, the essential components of pathogenicity, are toxic only to susceptible plants. These toxins produce visible disease symptoms of the resulting disease; that is, treatment with HST extracts alone induces the same symptoms as pathogen infection. HSTs were critical virulence factors

contributing to two devastating crop epidemics. The Southern corn leaf blight epidemic of 1970, caused by the pathogen *Cochliobolus carbonum* destroyed approximately 15% of the US maize crop. Symptoms on susceptible maize result from the production of a cyclic tetrapeptide called HC-toxin. The Victoria blight epidemic of oats in the mid-1940s was caused by *Cochliobolus victoriae*, which elicits symptoms caused by the cyclized peptide phytotoxin victorin.

Although most described HSTs are secondary metabolites, a few are proteins, such as ToxA, produced by *Pyrenophora tritici-repentis*, during the development of tan spot disease of wheat (Tomas *et al.*, 1990; Ciuffetti *et al.*, 1997). Although the pathogen secretes the toxin into the plant apoplast, ToxA must be internalized into susceptible wheat cells to have its toxic effect (Ciuffetti *et al.*, 2010). Resistant wheat cultivars do not internalize the toxin. Internalization is directed by a specific motif in ToxA that comprises Arg-Gly-Asp (RGD); this motif is predicted to interact with a plant membrane receptor that helps translocate the ToxA into the plant cell (Ciuffetti *et al.*, 2010).

General toxins, or nonhost selective toxins, are toxic to most plants, and have a broader host range than the producing pathogen. Often general toxins affect organisms beyond plants, including bacteria or yeast, a feature that has been exploited to study these toxins in systems simpler than plants. General toxins are not essential virulence factors; mutation of genes involved in the biosynthesis of these toxins does not render the pathogen avirulent. The mutant pathogen can still cause disease, but may be less aggressive. Coronatine, phaseolotoxin, and tabtoxin are three general toxins produced by the bacterial species in the *Pseudomonas* genus.

Some virulence effectors work as plant growth regulators, also called phytohormones. Phytohormones are molecules that regulate plant growth, at extremely low concentrations. Pathogen-produced auxins and cytokinins can induce developmental and morphological changes that can result in galls, epinasty, or a number of other grotesque shapes in the plant. The gram-positive bacterium *Rhodococcus fascians* synthesizes and secretes cytokinins that are taken up by the plant cells surrounding the infection site. These cytokinins activate a set of plant genes that keep the cells in a juvenile state, contributing to disease symptoms such as serrated leaves, stunting, and abnormal flowers (reviewed by Busch and Benfey, 2010). Besides inducing chlorosis and other disease symptoms, the general toxin coronatine produced by *Pseudomonas* spp. structurally and functionally mimics the plant hormone jasmonic acid isoleucine. In this role, coronotine promotes the opening of plant stomata, allowing the bacteria to enter the plant and access the apoplast (Melotto *et al.*, 2006; Thilmony *et al.*, 2006).

Effectors that are delivered to the inside of plant cells

Genome searches for signature signal domains has led to the discovery of large numbers of genes encoding effectors that could be translocated into the plant cytoplasm. For most of these putative effectors, the exact molecular target or role in the infection process is not known. The widely studied bacterial effectors delivered by the TTSS provide examples of the broad range of host pathways and functions that are targeted. Some TTSS effectors, such as the *P. syringae* effectors AvrRpt2 and AvrB, alter the hormone content of plant cells. AvrRpt2, a cysteine protease, stimulates turnover of proteins that negatively regulate auxin signaling to promote pathogenicity (Cui *et al.*, 2013). AvrB activates mitogen-activated protein kinase MAP kinase 4 (MPK4), which upregulates the expression of jasmonic acid response, a hormone perturbation that enhances plant susceptibility (Cui *et al.*, 2010).

Some microbial effectors function to actively suppress PTI, and thereby enhance susceptibility. One mechanism, employed by the *P. syringae* effector AvrPto, is to bind to and block the kinase activity of the PTI receptors (PRRs) that recognize several PAMPs. A second *P. syringae* effector AvrPtoB binds to and targets PRRs for degradation. Other effectors indirectly affect PRR signaling. Virulence effectors produced by some fungal pathogens, such as Sip1 produced by *M. oryzae*, bind the fungal PAMP chitin, thereby reducing the availability of the chitin for binding to the plant PRR, and inhibiting activation of PTI.

Still other effectors directly alter gene expression. The unique transcription activator-like (TAL) effectors produced and delivered to plant cells by *Xanthomonas* spp. enhance pathogen virulence by directly activating promoters of target plant genes associated with disease or susceptibility. These protein effectors contain a central repeat domain comprising 34–35 amino acid modules that are repeated in tandem; each repeat contains two hypervariable amino acid residues (for a review, see Scholze and Boch, 2011). The C-terminus carries signal sequences that direct the effector into the nucleus (nuclear localization signals; NLSs) and an acidic activation domain (AAD) characteristic of transcription factors. Once in the host cell, TAL effectors are targeted to the plant nucleus by the NLS. In the nucleus, the TAL effectors bind specifically to sequences in target plant gene promoters and induce expression of these plant genes. The DNA-binding specificity of TALs is determined by central hypervariable amino acid residues. Although the discovery and validation of the function of plant genes targeted by TAL effectors is in its infancy, some are known to activate expression of genes that enhance susceptibility. The *X. campestris* pv. *vesicatoria* effector AvrBs3 induces the expression of auxin-responsive genes in susceptible pepper plants; the resulting increase in auxin causes changes in cell division, cell enlargement, and hypertrophy, which may facilitate release of bacteria to the leaf surface and into the environment (Marois *et al.*, 2002; Kay and Bonas, 2009). AvrXa7 and PthXo1 produced by *Xanthomonas oryzae* pv. *oryzae* induce the expression of sugar transporters OsSWEET14 and OsSWEET11, respectively. The increased expression of these genes is predicted to enhance transport of sugar outside of the plant cell for bacterial consumption and thereby increasing the risk of disease (Chen *et al.*, 2010).

The few examples above demonstrate that pathogen effectors target a wide variety of plant functions to cause disease or increase pathogen fitness. However, functions are known for only a few effectors, mainly because the study of effector function is complicated by the large numbers of diverse effectors that any one pathogen secretes. *P. syringae* secretes more than 40 effectors (Chang *et al.*, 2005). Although some effectors are major contributors to pathogen virulence, most effectors likely function in concert to cause disease, with inactivation of multiple effectors needed to observe any change in virulence function (Cunnac *et al.*, 2009). As a better understanding of the effector function could reveal new strategies for disease control, effector biology remains a major research area.

Effector-Triggered Immunity: Evolution of Plants to Evade ETS

In response to the suppression or evasion of PTI by effectors, plants evolved a second line of defense called effector-triggered immunity (ETI). In ETI, plants use intracellular immune receptors that are the products of resistance (R) genes to monitor effectors or their activity and activate strong defense responses. ETI-associated defense responses frequently, but not always, are characterized by a rapid, localized programmed cell death (PCD) of the host cells called hypersensitive response (HR). Other localized host responses activated by ETI can include the production of reactive oxygen species, enhancement of cell walls, accumulation of toxic metabolites or proteins, and altered hormone regulation. In some cases, ETI results in a systemic activation of resistance, called systemic acquired resistance (SAR) or priming for a more efficient activation of defense mechanisms in response to a secondary pathogen attack (Conrath, 2011).

Flor (1971) first conceptualized the 'Gene for Gene Hypothesis' positing that R genes direct the recognition of pathogen avirulence genes (now called virulence effectors) to culminate in resistance. Many R genes and effector gene combinations have since been characterized, supporting the hypothesis. How the R proteins actually confer recognition, though, is still being discovered and debated (Zipfel and Robatzek, 2010). Most, but not all, R proteins contain nucleotide-binding (NB) and leucine-rich repeat (LRR) domains. There are two subclasses of these NB-LRR proteins; one with a coiled-coil (CC) domain and the other with a toll, interleukin-1 receptor, resistance protein domain (TIR) at the N-terminus (Bernoux *et al.*, 2011). Initially, R proteins were predicted to interact directly with their target effectors to activate defense in a ligand–receptor manner (Keen, 1990). Indeed, direct, physical interactions have been shown for some R/effector gene combinations. R proteins in rice (Pi-ta, Pik, and RGA4/RGA5) and flax (L-locus NB-LRR proteins) directly bind to translocated effectors produced by the fungal pathogens *M. oryzae* and *Melampsora lini*, respectively, to activate resistance (Jia *et al.*, 2000; Dodds *et al.*, 2006; Ellis *et al.*, 2007; Kanzaki *et al.*, 2012). For many R/effector gene combinations, however, direct interactions could not be detected.

With the realization that R gene partners were pathogen virulence effectors, and with the identification of plant virulence targets for several effectors, a new model was proposed. This 'Guard Model,' predicts that R proteins act by monitoring (guarding) the effector target (guardee), and that modification of this target by the effector results in the activation of the R protein, triggering disease resistance in the host (Jones and Dangl, 2006). An evolutionary assumption in this model is that the effector/guardee modification enhances the pathogen's fitness. Supporting the Guard Model, the *Arabidopsis* R-protein RPM1 directly interacts with and responds to the status of a plant membrane-associated protein RIN4. RIN4 is the target of multiple bacterial effectors, including the *P. syringae* effector AvrB, and AvrB-mediated phosphorylation of RIN4 activates signaling by RPM1 (reviewed by Chisholm *et al.*, 2006; Jones and Dangl, 2006). Thus, RPM1 (the guard) monitors the status of RIN4, and the change in RIN4 (the guardee) by pathogen effector activity triggers the defense response pathway.

Not all R/effector gene interactions fit the Guard Model, because fitness benefits could not be found for R-gene interactors. Therefore, a second model, the Decoy Model, was proposed (Zipfel and Robatzek, 2010). The Decoy Model predicts that the effector target monitored by the R protein is a decoy that mimics the effector target, but *only* functions in perception of pathogen effectors without contributing to pathogen fitness. An example of an interaction fitting this model is AvrPto, a TTSS effector produced by *P. syringae*. AvrPto is a kinase inhibitor that binds to the cytoplasmic Ser/Thr kinase domain of a PAMP receptor, blocking PTI and enhancing virulence of the pathogen. AvrPto also binds to the tomato R protein Pto. Pto confers resistance to *P. syringae* strains harboring *avrPto*, but only if the plant contains Prf, a protein that physically interacts with Pto. Binding of AvrPto to Pto is detected by Prf, and ETI is triggered. Thus, Pto is a decoy that binds AvrPto, and the interaction of Pto with AvrPto is detected by Prf for signaling of ETI.

Defense Response Pathways are Shared between PTI and ETI

Although the categorization of immunity into PTI and ETI may imply that these are totally distinct responses, in reality, there is a great deal of overlap in the molecular events induced by both PTI and ETI (Tsuda and Katagiri, 2010), and a continuum in the two categories is observed (Thomma *et al.*, 2011). For example, the downstream signaling machinery used and the defense genes activated by ETI and PTI overlap extensively, although the strengths of the responses and their duration vary considerably. ETI-activated responses are more prolonged and robust than those activated by PTI, and an interesting current hypothesis is that ETI is a faster and more robust reactivation of PTI (Tsuda and Katagiri, 2010). This is shown by the amplitude of the responses in the zigzag model (**Figure 2**).

How Does the Environment Impact Disease in the Context of Climate Change?

Crop production, with its wide geographical range and intensity, is clearly affected by climate change (Lobell and Gourdji, 2012). Climate change may cause unpredictable changes on pathogen populations in varying effects depending on the specific pathosystem (Newton *et al.*, 2012; Chakraborty *et al.*, 2000). Increased temperature results in more rust disease in wheat and oats, whereas forage species become more resistant to certain fungi. Temperature effects on disease levels can result from temperature-induced changes in the host, pathogen, or the host–pathogen interactions (Garrett *et al.*, 2006; Newton *et al.*, 2012). Host plant changes might include (1) the alteration of plant architecture to create more suitable microclimates for pathogen colonization, (2) changes in the effectiveness of plant disease resistance, and (3) the increase of stress on plants, all of which would affect disease development. Higher temperatures are predicted to accelerate the breakdown of plant disease resistance in many host–pathogen systems by increasing disease pressure and/or altering *R* gene efficacy (Garrett *et al.*, 2006; Coakley *et al.*, 1999; Webb *et al.*, 2010).

It has been documented that an increasingly warmer weather provides a first glimpse of the impact on disease distribution and changes in severity. A simple scenario is that warm temperatures will reduce the impact of cool season diseases. However, this assumes that the pathogen remains static. *Puccinia striiformis* causes stripe rust of wheat and barley, and is, in general, a cool season pathogen that does well in the Pacific Northwest of the USA (Chen, 2005; Hovmoller *et al.*, 2011). The pathogen was not a problem in the wheat belt of the US Great Plains before 2001, because the fungus could not thrive in the warmer weather of this region. Unfortunately, a variant of the pathogen that is more adapted to higher temperatures appeared in the Great Plains in the early 2000s, and stripe rust is now a serious problem in this region.

Applying Knowledge of Plant–Microbe Interactions to Disease Control Strategies

What is out There?

Diverse groups of organisms are capable of causing plant diseases, and many management strategies to control these pathogens vary according to the specific pathogen. Thus, a first step in controlling plant disease is to accurately identify the cause. Diagnosis is based on the presence of symptoms and signs in the diseased plant. Symptoms are phenotypic expressions of disease in a plant in response to activities of the pathogen, including pathogen effectors. The symptoms may be localized to specific plant tissues, or systemic, as in the case of diseases caused by viruses and vascular wilt pathogens. Symptoms include those that cause plant death or necrosis (e.g., lesions, cankers, and rots), or those that result in hypertrophy and hyperplasia of tissues as in the case of galls and witches' brooms (Figure 5). Although symptoms are often helpful in field diagnosis, they may be misleading because completely unrelated pathogens can cause nearly identical symptoms. Furthermore, the interaction phenotype resulting from infection may vary depending on environmental conditions or the age and genetic background of the plant. Thus, diagnosticians often rely on signs, or visual confirmation of the pathogen in host tissue, for disease identification. Some signs, including bacterial ooze or fungal hyphae and fruiting structures (Figure 5) may be readily seen in the field. However, most pathogen signs are visible only by using a hand lens or microscope. In some cases, pathogens must be cultured or identified by serological and molecular detection methods.

Pathogens Function as Populations

While in the laboratory, the focus of the researchers was on characterizing how single 'model' pathogen strains cause disease; disease at the field level is not caused by a single pathogen genotype. To cause disease, the pathogen functions

Figure 5 Signs and symptoms of plant disease. (a) *Botrytis* blight of juniper; mycelium (sign) of *Botrytis cinerea* showing brown decay (symptoms). (b) Symptoms of late blight of potato. (c) and (d) Fruiting structures (sporangia) and mycelium of *Plasmopara viticola*, causing downy mildew of grape. Photos provided by Ned Tisserat.

as a population that is made up of multiple genotypes or strains with unique genetic and pathogenic attributes. The pathogenic attributes of the entire pathogen population collectively determine the ability to cause disease, the amount of disease on a plant and in a plant population, and the epidemiological consequence on the plant population. The primary evolutionary forces that shape a pathogen population include mutation, population size, gene/genotype flow, reproduction system (asexual vs. sexual), and selection imposed on the pathogen by the host and environmental factors (McDonald and Linde, 2002). The interactions of these evolutionary forces shape the genetic structure of the pathogen population.

Pathogens with high mutation rates, large population size, mostly asexually reproducing but with occasional sexual recombination, high dispersal over distance (gene flow), and under strong directional selection by the host are considered to have the highest risk potential. In contrast, pathogens with low mutation rate, relatively small population size, short dispersal, limited recombination, or gene flow present lesser risk in an agroecosystem. This broad characterization of pathogen populations provides a useful framework for disease resistance breeding and disease management. However, ability to effectively manage a pathogen requires detailed and specific knowledge of the pathosystem, and the strategies employed must be flexible to adjust to changing agricultural production systems and physical environments.

Use of Disease Resistance Gene for Pathogen Control

Genetic resistance has been the mainstay of disease control for many crop species. The two broad categories of host resistance are major gene resistance and quantitative resistance. As discussed earlier, major gene resistance is primarily involved in ETI whereas quantitative resistance involves basal defenses triggered by PTI, recognizing that there are considerable overlaps in the mechanisms triggered by ETI and PTI. Under strong directional selection, as in the case of major gene resistance, one or a few adapted pathogen strains will predominate the pathogen population, leading to severe epidemics. However, selection imposed by quantitative resistance is predicted to be less, reducing the pressure on pathogen population to evolve toward high aggressiveness. In agronomic terms, major gene resistance provides a 'clean' crop but with uncertainty about its stability. Quantitative resistance, however, allows some level of disease development but offers stability. Unlike major R genes that can be dramatically overcome by simple mutations of major genes in the pathogen, quantitative resistance is predicted to be 'eroded' over time through gradual changes of pathogenicity genes to counteract the defense mechanisms imposed by the host (McDonald and Linde, 2002; Lannou, 2012). Finding the right combination of major and quantitative resistance to provide effective and potentially durable resistance is the goal of many plant breeding programs.

Pathogen Fitness Penalty as a Predictor of R Gene Durability

More than 50 years ago, Vanderplank (1963) proposed that a pathogen with unnecessary virulence has lower parasitic fitness on the host without the corresponding resistance. Intuitively, accumulation of mutations in avirulence effector genes to avoid recognition by major resistance genes would reach a point to reduce the overall fitness of the pathogen population. The fitness penalty concept is useful in that it suggests practical applications. In a simple case, if an avirulence gene codes for a product with important functions other than being a target of recognition by the host, a loss-of-function mutation would be disadvantageous to the pathogen. It follows that measuring the fitness penalty of mutation from avirulence to virulence can provide a predictor of the effectiveness of the corresponding R genes, which collectively (as in a gene pyramid) result in durability of resistance (Leach *et al.*, 2001). Although there are pathosystems that seem to follow this general 'rule,' for example, bacterial blight of rice (Vera Cruz *et al.*, 2000), there are cases where a pathogen carrying unnecessary virulence does not exhibit lower parasitic fitness. For example, Chen (2005) studied the virulence spectrum of *Puccinia striiformis* f. sp. *tritici* and *Puccinia striiformis* f. sp. *hordei*, two closely related pathogens, and noted that races of *P. striiformis* f. sp. *tritici* with wide virulence still dominated the population. In contrast, *P. striiformis* f. sp. *hordei* races with narrow virulence tended to predominate, as predicted by the fitness penalty hypothesis.

The long history of coevolution between the pathogen and host would guarantee that the pathogen has evolved multiple mechanisms to compensate the fitness penalty caused by mutation of a single avirulence effector gene. One scenario is that the pathogen can have multiple copies of related effector genes that provide the necessary functions. Secondary mutations at different loci may compensate for the primary function of the first mutated gene. Thus, understanding the biology of changes from avirulence to virulence is essential to effectively apply the fitness penalty concept in managing diseases.

With advances in knowledge of the genetic and molecular basis of avirulence effector genes (Win *et al.*, 2012), there are now more tools to test the fitness hypothesis. For example, in the blast fungus *M. oryzae*, 15 Avr genes have been identified and isolated (reviewed by Liu *et al.*, 2013). By genome sequencing, a further 851 genes in *M. oryzae* are predicted to produce effector proteins (Chen *et al.*, 2013). Similarly, with large repertoires of confirmed and predicted effector genes, it is now possible to genetically inactivate avirulence effector genes individually or in combinations and measure whether their fitness attributes, such as reproductive rate (fungal spore production, bacterial multiplication), latent periods, and infection efficiency under laboratory or greenhouse settings. A caveat of this approach is that these standard fitness attributes may not be the only ones that are important in the natural environment where the pathogen has to survive and compete in the presence of the host and under harsh environments.

An alternative and complementary approach would be to conduct field survey studies to test the association of avirulence effector genes in natural populations. For known effector genes, it is possible to test if avirulence gene combinations exist in random or significantly deviate from random in the natural populations. If some combinations occur much less frequently than expected, it would suggest that the corresponding R gene combinations are more effective. By

monitoring the frequency of avirulence gene combinations, it may be possible to reveal the R gene combinations that are more effective.

The approach of testing gene associations for the whole pathogen genome, including genes for effectors as well as quantitative pathogenicity in the pathogen, can be generalized by applying genome sequencing to characterize pathogen populations. By combining sequence and pathogenic attributes, genome-wide association studies (GWAS) can be done comparable to what has been practiced in humans, animals, and plants. Several pathosystems, such as cereal rusts, rice blast and bacterial blight, and potato late blight are particularly amenable for applying GWAS, considering their global importance. The alarming spread of the stem rust strain Ug99 since its detection in 1999 in Uganda (Singh *et al.*, 2011) would present an interesting case to examine genome-wide changes of the new strains spreading over a broad geographic region.

Combining Major R Genes and QTL

Despite the concerns of 'breakdown' and 'erosion' of disease resistance, there are examples where a combination of major R genes and QTL provide stability of resistance in a farmer's field. Liu *et al.* (2009) dissected the genetic basis of resistance in a rice variety Shan-Huang-Zhan number 2 (SHZ-2) that has a reputation of exhibiting durable resistance to rice blast in South China. SHZ-2 has multiple major R genes and QTL. Some of the R genes are in clusters rich in NBS-LRR genes (Liu *et al.*, 2013). SHZ-2-derived lines have been tested in disease hot spots and continue to show stable resistance for more than 10 cropping seasons (Manosalva *et al.*, 2009). Owing to its performance and the known underlying genetics, SHZ-2 has been used as a donor of blast resistance in breeding programs in Southeast Asia.

There are also examples of atypical R genes providing effective disease control. A classic example is the recessive gene *mlo* for barley resistance against powdery mildew (*B. graminis* f. sp. *hordei* (Jørgensen, 1992). The wild-type *Mlo* locus encodes a seven-transmembrane protein, which functions as a negative regulator of resistance to powdery mildew and could have a broad role in regulating resistance to biotic and abiotic stress (Piffanelli *et al.*, 2002). Since 1979, barley varieties carrying *mlo* resistance have been shown to be effective over large areas, satisfying the criteria of 'durable resistance' (Lyngkjær and Ostrergård, 1998). More recently, a recessive gene conferring blast resistance in rice was isolated and characterized. In contrast to the majority of blast resistance genes (*Pi* genes), which encode NB-LRR proteins, *pi21* encodes a proline-rich protein (Fukuoka *et al.*, 2009). The *pi21* recessive mutation is associated with durable resistance to blast in the upland rice grown in Japan. However, the area planted to varieties carrying *pi21* is relatively small. The effectiveness of *pi21* needs to be tested in varieties planted widely in intensive production system. Regardless, *pi21* is a welcome addition to the pool of resistance genes that are not NB-LRR types.

Another successful case of achieving durable resistance is the use of high-temperature adult plant (HTAP) resistance to manage stripe rust of wheat (Xu *et al.*, 2013). The effectiveness of this type of resistance depends on the age of the plant and high temperatures. Although used to control stripe rust for more than 60 years in the US, the genetic mechanisms of HTAP resistance were recently revealed through the characterization of the HTAP gene *Yr36* (Fu *et al.*, 2009). *Yr36* is upregulated by high temperature, explaining the phenotypic expression. In contrast to most NB-LRR genes for strong ETI-type resistance, HTAP resistance provides partial but stable resistance against stripe rust over time.

Plant Diversity to Manage Disease

The benefits of using plant diversity to manage diseases or enhance crop performance are generally recognized. However, there is much debate in the approaches of how to effectively deploy genetic diversity in modern agricultural systems. Diversity can be deployed at a single genotype level, or diversity could be used at the population level in a plant community.

Many major crop breeding programs have introduced more genetic diversity into the crops. For example, the 'Green Revolution' for rice production began with the release of the first semidwarf rice variety IR8 in the mid-1960s. IR8 has only three landraces in its pedigree. Though breeding efforts have focused on improving disease and pest resistance and grain quality, diversity was systematically incorporated into modern rice varieties derived from IR8 (Peng *et al.*, 2008). In contrast to IR8, the pedigree of the modern variety IR64, released in the mid-1980s, includes 20 landraces. IR64 is grown over millions of hectares in tropical Asia, partly because it has shown good resistance to rice blast for more than two decades since its release. The accumulation of diverse genes contributes to the stability of disease resistance observed in IR64. Thus, using a broad genetic base and practicing appropriate selection can play a key role in developing disease-resistant varieties.

Multilines and varietal mixtures

Besides combining diverse genes in a single genotype, individual genes can be used separately in time and space. The basic principle of having different host genotypes in a field is to reduce the selection pressure toward more virulence in the pathogen populations. Multilines carrying up to 10 individual resistance genes are being used for controlling crown rust in oats, and are currently being used to manage rice blast in some areas of Japan (Abe, 2004). In practical breeding, multilines fit a specific niche where resistance genes are added to a single genetic background to control disease. A main limitation of the multiline strategy is that much time and effort is needed to produce near-isogenic lines with individual resistance genes. Very often, by the time near-isogenic lines are produced, their other agronomic attributes are surpassed by other improved varieties. Wolfe (1985) advocated the use of varietal mixtures, a strategy that uses a mixture of varieties that are agronomically homogeneous but genetically diverse with respect to disease-resistance genes. The system is expected to stabilize the selection on the pathogen population. This strategy alleviates the need to produce isogenic lines and captures the complementary agronomic attributes provided by multiple varieties.

Interplanting

Interplanting resistant and susceptible varieties in different ratios is another strategy that capitalizes on diversity to control

disease. This strategy was deployed to control rice blast disease in a large-scale experiment in the Yunnan province of China (Zhu *et al.*, 2000). Disease was reduced by 94% in the interplanted plots compared with the monoculture plots. In this experiment, the susceptible was glutinous rice, which is 20 cm taller than the resistant variety (**Figure 6(a)**). The height difference may alter the microclimate of the canopy to become less conducive to disease development. Owing to the success of the interplanting experiment, and because glutinous rice has a high market value, the interplanting strategy was adopted in more than a million hectares of rice production (**Figure 6(b)**). Although interplanting may not be applicable to all crops and cropping systems, its success raised awareness of the importance of plant diversity for managing diseases.

Other Disease Control Strategies

Plant diseases cannot always be controlled by resistance. Resistance genes to a specific pathogen may not be available in certain plants, or the suite of quantitative resistance genes in some plants may not provide a sufficient level of control. In other cases, resistance genes may be difficult to incorporate (as in many woody perennials) or they may be linked to agronomically unsuitable traits. Therefore, other management strategies are needed to suppress pathogen populations and disease development, sometimes even where resistance is the primary means of controlling disease. Some diseases can be avoided by growing crops in regions that are not conducive to disease development. For example, many vegetable crops grown for seed are produced in arid regions of the western US, where low rainfall and a lack of extended leaf wetness necessary for infection inhibits foliar and seed pathogens. Plant pathogens may be excluded during a growing season by using pathogen-free seed or propagative parts. Heat treatment and meristem tip culturing are used to rid plants of viruses and hot water treatments can disinfest seeds of surface contaminating bacterial pathogens.

Once introduced into an area, pathogens (other than biotrophs) can rarely be eradicated, but their populations can be reduced by certain cultural practices. Crop rotation is an excellent method of reducing inoculum levels of some pathogens that exhibit host specificity. Plowing pathogen-infested plant residue into the soil at the end of the season hastens its decomposition and may reduce populations of pathogens that are not good soil inhabitants. Although the practice of reduced tillage has been widely adopted by farmers to prevent soil erosion and to conserve soil moisture, it may have the undesirable consequence of enhancing pathogen survival in crop debris. Goss's wilt, a bacterial disease of corn, has recently increased in severity in the Great Plains of the US in part because of widespread adoption of reduced tillage practices and a lack of crop rotation.

Many bacterial, fungal, and oomycete diseases are managed by chemical applications. Copper-based products, and to a much lesser extent antibiotics (streptomycin sulfate and tetracycline), are used for bacterial diseases whereas a broad array of fungicides with varying modes of biochemical action control oomycetes and fungi (see http://www.frac.info/publication/publication.htm). Fungicides are generally classified as protectants (also called contacts) or systemics. Protectants are not absorbed and redistributed but instead form a protective barrier on the plant surface. They, for the most part, affect multiple biochemical pathways in pathogens and are not prone to resistance problems. Some systemic fungicides are absorbed and move only in the leaf on which they were applied; others move acropetally in the xylem. Only the phosphonate fungicides are capable of acropetal and basipetal movement. Most systemic fungicides target specific enzymes in fungal or oomycete biochemical pathways and are therefore at a higher risk for fungicide resistance due to selection pressure in the pathogens. For example, there are numerous cases where mutations in the demethylase gene of fungal pathogens render them less sensitive to demethylation-inhibiting fungicides. Fungicide resistance is a major concern, and strategies such as avoiding multiple

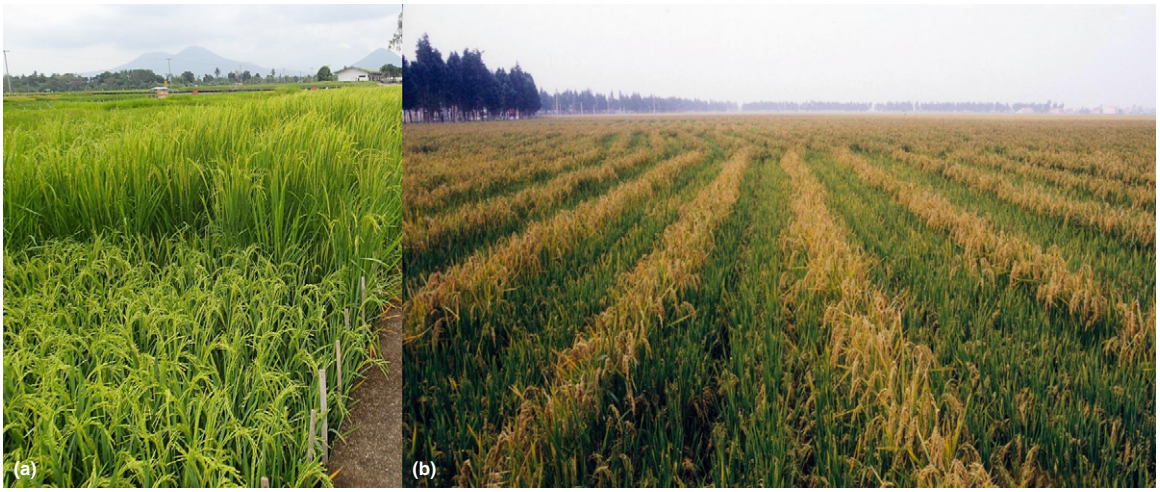

Figure 6 Interplanting of glutinous and hybrid rice to avoid rice blast disease in Yunnan, China. (a) Blast-susceptible glutinous rice (foreground) is 20 cm shorter than the blast-resistant hybrid rice (back). (b) Alteration of four rows of glutinous (short) rice with one row of the hybrid (tall) rice was very effective at reducing blast disease on the glutinous rice. applications of the same fungicide during the growing season or mixing or rotating different classes of fungicides have been recommended.

Concluding Perspectives

Much progress has been made in understanding the molecular evolution of plants and pathogens, and the integration of this information into crop improvement programs or for disease management is ensuring sustainable crop production for the immediate future. Still, the functions for very few pathogen effectors are known, and often these are only in model systems. Our knowledge is limited on how plant defense responses are differentially regulated or modulated in the spectrum from PTI to ETI, and how this regulation can be manipulated for better disease control. As an example, the relevance of epigenetic controls on plant disease and immunity is only just beginning to be addressed (Alvarez *et al.*, 2010).

Most of our knowledge has been gained by studying plant–microbe interactions in growth chambers and greenhouses, and rarely, in fields under conditions typical for a given disease. As a result, little is known about the interactions of environment with disease development, PTI, or ETI. The trend toward systems approaches to study how plant and pathogen genomes, metabolomes, and physiology are affected by interactions with each other and with environmental changes is a promising start, but frequently they are limited to growth chamber or greenhouse studies. The design of proactive disease management strategies for globally important diseases will require new experimental strategies. One possibility is to establish 'biostations' where disease can be assessed using a common set of genetic materials over different geographic areas with a range of climate scenarios.

Evolving new, improved, or cheaper technologies, such as genomics, proteomics, metabolomics, and high throughput phenotyping capacity at the field level, will provide deeper insights into plant disease and resistance. The integration of the molecular, organismal, and systems-level information gained from using these approaches will ultimately allow improvement of disease management strategies to include broad-spectrum and durable disease resistance.

Glossary

Allee effect An effect in low-density populations where average per capita fitness increases with population density through increased efficiency of mating, food acquisition, or natural enemy escape.

Arthropod Any animal in the phylum Arthropoda that includes insects, mites, and other invertebrate taxa that are characterized by a chitinous exoskeleton, segmented body, and jointed limbs.

Ecosystem service Products and processes provided by natural ecosystems that are critical for human well-being.

Entomopathogen A bacterium, virus, protozoan, or fungus that causes disease in insects.

Epizootic An outbreak of disease in a population of the same animal species.

Hyperparasitism Occurs when a parasitoid species uses another parasitoid species as the host for its own larval development.

Irreplaceable mortality The mortality that would not occur if a specific mortality factor was removed, taking into account the compensating action of other mortality factors.

Parasitoid An insect with a parasitic larval stage that develops by feeding in or on the body of a single insect or other arthropod host.

Introduction

Biological control is a valuable ecosystem service that describes the suppression of an insect pest population by one or more living organisms that are known as natural enemies. Insect pests are broadly considered to include all populations that cause harm to humans and their agricultural resources, whereas natural enemies are more narrowly restricted to living predators, parasitoids, competitors, and entomopathogens (including nonliving, but replicating viruses). A number of other biological approaches to the management of insect pests have at times been considered to be biological control tactics, and these include host plant resistance, transgenic insecticidal crops, insect growth regulators (IGRs), botanical insecticides, pheromone disruption techniques, and sterile insect techniques. Although these valuable control tactics play an important role in insect pest management, they are distinct from biological control covered in this article in that they are not based on the ecological interactions between agricultural resources, target pests, and natural enemies.

The suppression of an insect pest population by natural enemies can occur naturally and unaided by humans, or can be facilitated by human intervention. It is the dynamics of the underlying ecological interactions that characterize biological control, and the traits of the species involved and the favorability of the abiotic and biotic environment that influence the strength of the interactions and consequently the degree of insect pest suppression that can be achieved. Thus, biological control involves both direct and indirect interactions (Moon *et al.*, 2012) between insect pests, natural enemies, and agricultural resources with humans playing an important role in both reaping the benefits and facilitating the other interactions (**Figure 1**). The direct interactions are those that occur between two species via various forms of consumption, such as predation, parasitism, or infection by the natural enemy, herbivory by the insect pest, and the contribution of agricultural resources to human welfare. The indirect interactions are more subtle and necessarily involve a third species, such as the indirect benefits of natural enemies for both humans and agricultural resources via suppression of insect pests, and the indirect control of an insect pest by a nondamaging competitor acting as a natural enemy via induced crop resistance to the insect pest. Although natural enemies seldom act as indirect suppressors of insect pests, it is a common mode of action for natural enemies (such as microbial antagonists) used in the suppression of plant diseases. Some notable exceptions, however, include the introduction of dung beetles for the suppression of bush fly populations in Australia, which compete for the removal of dung from cattle ranches (Tyndale-Biscoe and Vogt, 1996), and the induction of plant resistance by early season Willamette mites in vineyards in California to suppress populations of the later-season, more damaging, Pacific mites (Karban *et al.*, 1997). In addition, biological control can involve even more complex interactions, such as the mutualistic interactions between grasses and their endophytic fungi, *Neotyphodium* species (Hartley and Gange, 2009). By production of toxic alkaloids the endophytes can either deter, or reduce the performance of, insect herbivores as an example of a direct antagonistic interaction. In some cases, however, the endophytes may also cause an indirect negative effect on the performance of predators and parasitoids due to a reduction in the nutritional quality of the insect herbivores. The net effect of this mutualism is often beneficial in terms of the biological control of insect pests of pasture grasses, but can also depend on fungal and grass genotype, fungal, grass and insect species, and environmental conditions.

The application of biological control for the suppression of insect pests dates back some 3000 years in documented records, when weaver ant nests were collected from mountain forests and established on trees in citrus groves in China (Olkowski and Zhang, 1998). Weaver ants are effective predators of a number of citrus pests, and these and similar ant species continue to play a very important role in the suppression of insect pests in citrus production in many parts of

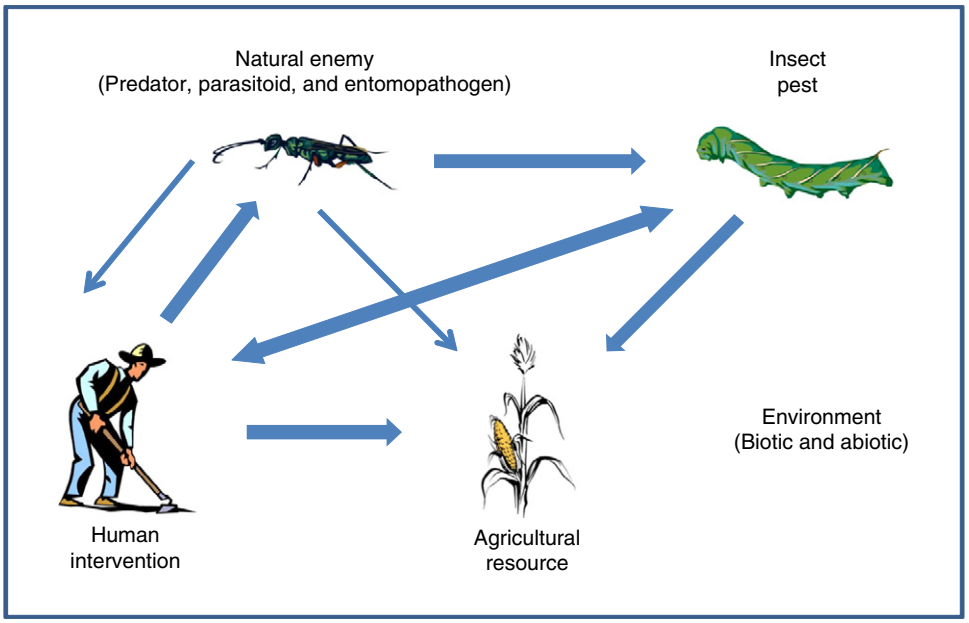

Figure 1 A diagram of the ecological relationships that characterize biological control. Direct interactions are shown by thick lines (direct trophic interactions with arrows pointing to the resource, direct competitive interaction with arrows at both ends), and indirect interactions by thin lines (with arrows pointing to the beneficiary).

the world. The original success of the weaver ants in citrus groves in China was further facilitated by surrounding the base of the citrus trees with moats to prevent ants from leaving the tree canopies, and by providing bamboo bridges between trees to encourage the spread of their foraging activity. This early record of the use of ants as natural enemies for the suppression of citrus pests is an example of augmentative biological control, one of four approaches to biological control that have since become recognized in insect pest management. The four approaches are (1) natural biological control, i.e., the natural suppression of potential insect pests by resident natural enemies that requires no human facilitation, (2) importation biological control, i.e., the deliberate importation and establishment of specialized natural enemies from the region of origin of an exotic invasive insect pest to provide long-term suppression over broad geographic regions, (3) conservation biological control, i.e., the localized manipulation of the crop environment to protect or enhance the activity of resident natural enemies for short-to longer-term suppression of insect pests, and (4) augmentative biological control, i.e., the mass production and localized release of resident natural enemies to augment their abundance for either immediate (inundation) or season-long (inoculation) suppression of insect pests.

Natural Biological Control

It is well known that only a minority of insect species ever achieve the status of an agricultural pest, in part because many of them do not live on cultivated plants but, more importantly, because the abiotic and biotic environment is often not favorable for their population growth. Environmental favorability is influenced by abiotic factors that can affect a potential insect pest either directly via tolerance of physical, chemical, or climatic conditions, or indirectly through their influence on the nutritional quality of cultivated plants. For example, heavy rains not only lead to direct mortality of plant-feeding insects, but can also lead to improved host plant quality through the stimulation of plant growth. Similarly, environmental favorability is influenced by biotic factors that, in addition to host plant quality, include host plant abundance, activity of competitors and natural enemies, and disturbance from human intervention. Given the broad range of factors that contribute to environmental favorability, what evidence do we have that natural biological control ever plays a pivotal role in the suppression of potential agricultural pests?

The best evidence for natural biological control comes from unintended consequences of the use of synthetic pesticides. Populations of natural enemies tend to be impacted to a greater extent by pesticide use than populations of insect pests due to the loss of their food supply and perhaps also to an increased level of exposure (from a combination of greater mobility on plant surfaces and their smaller size and consequently greater surface area to volume ratio) and reduced level of general detoxification mechanisms (mixed function oxidases used by plant-feeding insects to breakdown chemical plant defenses). One experimental approach used to verify the role of natural enemies in the suppression of arthropod pests is referred to as the 'insecticidal check method' and was used, for example, by Morris *et al.* (1999) to demonstrate the effectiveness of the mite predator, *Neoseiulus fallacis*, in suppressing the abundance of the twospotted spider mite, *Tetranychus urticae*, in mint fields in central Oregon. Similarly, several studies have highlighted the importance of surface-dwelling predators in the biological control of planthoppers in tropical irrigated rice fields. Settle *et al.* (1996) demonstrated this very effectively in an experimental field study in Indonesia, where one half of the replicated plots were treated with a

combination of carbamate and organophosphate insecticides and the other half not treated (Figure 2). Rice brown planthopper, *Nilaparvata lugens*, showed a classic pattern of late-season resurgence in population abundance due to reductions in the abundance of surface and aquatic predators.

Even more impressive as a demonstration of the significance of natural enemies in the suppression of potential insect pests is the disruption of natural biological control in seminatural habitats. Repeated applications of malathion bait as part of an eradication program for Mediterranean fruit fly, *Ceratitis capitata*, caused disruption of the natural biological control of an endemic gall midge, *Rhopalomyia californica*, in the southern part of the San Francisco Bay Area of California (Ehler *et al.*, 1984). The gall midge produces multichambered galls on the terminal shoots of an indigenous coastal shrub, *Baccharis pilularis*, and its resident natural enemies consist of seven solitary parasitoid species that attack the juvenile stages of the gall midge. Total parasitism in galls was severely impacted by the eradication sprays that took place in 1981–82, and gall midge populations, released from parasitism, rapidly increased in abundance from less than 20 larvae per 100 terminals to nearly 800 larvae per 100 terminals. Ehler and Kinsey (1991) note that it was not until 7 years after the eradication program that the abundance of gall midges returned to normal and that parasitism was comparable in both sprayed and unsprayed areas. This example provides an excellent illustration of the pivotal role played by natural enemies in seminatural ecosystems and a perfect recipe for transforming the status of an indigenous plant-feeding insect from an innocuous curiosity to a major, albeit temporary, pest.

These case studies provide powerful examples of the potential of natural biological control to contribute to the unfavorability of an environment for plant-feeding insects and, consequently, to prevent them from achieving pest status. But how general are these patterns, and what do we know about the broader importance of natural biological control relative to other factors that influence the favorability of an environment in suppressing the vast majority of plant-feeding insects to nondamaging levels of abundance? From an analysis of life table data collected from 79 different plant-feeding insects, Cornell *et al.* (1998) found that natural enemies were responsible for a greater level of mortality than any other mortality source and that their impacts were generally greater in agricultural than in natural habitats. Although this does not mean that natural enemies act alone in suppressing the abundance of plant-feeding insects, it does suggest that natural

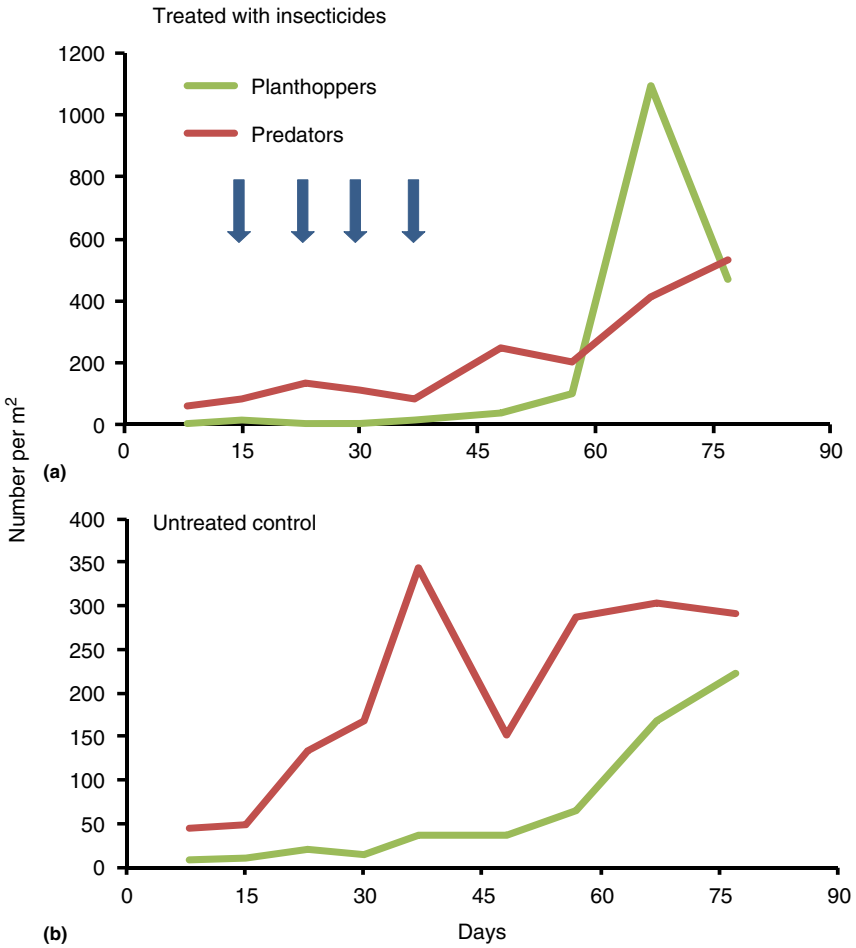

Figure 2 The abundance of brown planthoppers and their predators in rice fields in Java that were either treated with insecticides or left untreated as a control. Blue arrows indicate timing of insecticide treatments. Redrawn from Settle, W.H., Ariawan, H., Astuti, E.T., *et al.*, 1996. Managing tropical rice pests through conservation of generalist natural enemies and alternative prey. Ecology 77, 1975–1988

biological control may be more widespread in both cultivated and natural habitats than is generally appreciated.

Whenever resident natural enemies have the ability to suppress the abundance and activity of insect pests, their action is referred to as natural biological control. However, there can be many reasons why resident natural enemies may fail to provide sufficient suppression of insect pests in agricultural habitats. One clear reason is that the majority of our food and fiber crops are exotic to the geographic regions in which they are currently grown and are inevitably vulnerable to accidental invasions of exotic insect pests that are associated with these plants in their ancestral region. In general, resident natural enemies are poorly adapted to exotic insect pests and, consequently, are unable to suppress their abundance. In addition, modern conventional cropping systems are characterized by high-yielding varieties and intensified use of fertilizers, irrigation, pesticides and mechanization, and each one of these facets of modern agriculture can be responsible for disruption of the balance between insect pests and their natural biological controls. For example, crop domestication and the selection of high-yielding varieties have altered plant morphological traits that can act as barriers for natural enemies and provide direct benefits to insect pests, such as the olive fruit fly, *Bactrocera oleae*. Commercial olive varieties have greater pulp thickness than wild olives, which not only allows a greater number of individual larvae to develop per fruit, but also allows larvae to burrow to greater depths in the pulp where they experience less parasitism from specialized parasitoids, such as *Psyttalia lounsburyi*, due to short ovipositor lengths (Wang *et al.*, 2009). In addition to morphology, a suite of other plant traits, such as the herbivore-induced plant volatiles that are used by natural enemies as cues for host location, can also be influenced by crop domestication and crop variety with the potential to disrupt natural biological control (Gols *et al.*, 2011). Similarly, intensified use of fertilizers and irrigation typically improve the nutritional quality of crop plants and increase their susceptibility to insect pests, whereas pesticides, as noted above, can be particularly detrimental to natural enemies. Under these circumstances it may be possible to improve the biological control of insect pests through deliberate human intervention and the restoration of natural enemy populations.

Importation Biological Control

Importation biological control is an approach that focuses on the importation and establishment of specialized natural enemies from the region of origin of exotic insect pests. This approach is also referred to as classical biological control or biological control introduction. Exotic insects typically arrive in a new geographic region without their coevolved natural enemies, and resident natural enemies are unable to adapt to these novel hosts rapidly enough to provide effective biological control. Consequently, in being released from natural biological control, exotic insects often increase in abundance and expand their geographic range to become invasive and damaging pests, particularly in agricultural crops. The approach of importation biological control is for humans to deliberately import and establish specialized natural enemies from the region of origin of an exotic pest in an attempt to restore the ecological interactions that provide the natural biological control in the ancestral range of the pest.

One of the earliest and best known examples of importation biological control is the complete suppression of cottony cushion scale, *Icerya purchasi*, in citrus groves in California through the importation and establishment of the vedalia beetle, *Rodolia cardinalis*, from Australia in 1889 (Caltagirone and Doutt, 1989). The success of this ladybird beetle as a predator of the scale can be attributed, in part, to its specialization on the scale insect pest, and to its efficiency in responding to the volatile cues associated with its prey (Quezada and DeBach, 1973). More importantly, however, it has a shorter generation time than its prey, completing 10 generations per year in comparison to the three generations per year of the cottony cushion scale. Despite the greater per capita fecundity (325–450 eggs) of the cottony cushion scale compared to the vedalia beetle (150–190 eggs), and its hermaphroditic reproduction, the generation time ratio provides the vedalia beetle with a strong numerical advantage that is sufficient to drive the dynamics of the predator–prey interaction (Kindlmann and Dixon, 1999).

There were two important spin offs from this early success in the biological control of cottony cushion scale in California. One was that the success was repeatable, such that cottony cushion scale has subsequently been successfully controlled through importation of the vedalia beetle in most other citrus growing regions of the world. This repeatability, together with occasional observations of resurgence of cottony cushion-scale populations due to disruption of vedalia beetle populations by insecticide use in citrus, provides unquestionable proof of the potential for specialized natural enemies to provide effective and sustainable suppression of insect pests. A second spin off was that the dramatic success led to a brief worldwide infatuation with ladybird beetle species as effective natural enemies for importation biological control. Although this infatuation failed to result in other examples of success, it did generate the valuable insight that the probability of success of a biological control importation is not so easy to predict. As a result, we can now explain why the importation of the vedalia beetle proved to be so successful (Quezada and DeBach, 1973; Kindlmann and Dixon, 1999), and we have a much better appreciation of the importance of life history traits and foraging efficiency in determining the dynamics of the ecological interactions that form the basis for importation biological control (Mills, 2006; Murdoch *et al.*, 2006).

From a global perspective, there have been numerous programs developed in almost all parts of the world to manage invasive insect pests through importation biological control, and this has been the most extensively practiced of any of the approaches to biological control (Mills, 2000, 2006). There have been many other notable successes and, in general, parasitoids have been imported more frequently than predators, whereas entomopathogens have been used only rarely albeit with surprising success in the case of viruses. The majority of successes have been associated with sap-sucking pests (Hemiptera: Sternorrhyncha) and with tree crops to a greater extent than row crops. Thus it seems likely that both life history traits of the insect pests and frequency of disturbance of the agricultural habitat could be responsible for such patterns.

One of the largest scale projects ever conducted for importation biological control was the successful control of the cassava mealybug, *Phenacoccus manihoti*, an accidental introduction to the continent of Africa in the early 1970s from its ancestral home in Paraguay and Brazil (Herren and Neuenschwander, 1991). It spread from its initial points of introduction in Zaire and Congo at a rate of up to 300 km per year, and by 1990 it had covered most of the 10 million hectares of cassava production across the central belt of Africa, a region that is larger than the United States and India combined. Numerous national and international organizations collaborated in this program, which began with extensive foreign exploration for natural enemies in Central and South America. Following the discovery of the specialized parasitoid *Anagrus lopezi* in Paraguay, it was imported and established throughout the cassava-growing region through an extensive rearing and release program carried out in Benin by the International Institute of Tropical Agriculture. The parasitoid proved to be a tremendous success in suppressing the devastating damage caused by the cassava mealybug, and consequently it restored the exotic yet staple food supply of more than 200 million people across the central African belt (**Figure 3**). The significance of the project was recognized in 1995 by the award of the World Food Prize to Dr Hans Herren who had initiated and coordinated the project from the Biological Control Center for Africa in Cotonou, Benin. The success of the project was again due to the strength of the ecological interaction between *A. lopezi* and its host. In this regard, *A. lopezi* shares a number of traits in common with the vedalia beetle, namely specialization on the target pest, efficient host search through response to volatile chemical cues released from mealybug-infested cassava plants, a numerical advantage from a shorter generation time than its host, and the combination of a predatory adult life stage with a parasitic juvenile life stage (Herren and Neuenschwander, 1991; Nadel and van Alphen, 1987; Neuenschwander, 2001). In this case, however, the success of *A. lopezi* may also have been linked to its ability to produce female offspring from earlier instars of its mealybug host than was the case for other indigenous and exotic parasitoids (Gutierrez *et al.*, 1993). It also proved to be able to drive the dynamics of the underlying host-parasitoid interaction despite heavy levels of hyperparasitism (Neuenschwander, 2001), a trait that was also evident in the successful control of the walnut aphid, *Chromaphis juglandis*, in California through the importation of a parasitoid *Trioxys pallidus* from Iran in 1969 (van den Bosch *et al.*, 1979).

As noted earlier, viruses have been particularly successful in importation biological control, and this is well exemplified by the suppression of the rhinoceros beetle, *Oryctes rhinoceros*, a pest of coconut, oil and other palm trees in the tropical Asia/Pacific region. Adults are the damaging life-stage of the rhinoceros beetle and feed in the crown of palms causing wedge-shaped cuts in the unfurled foliage and even death of the

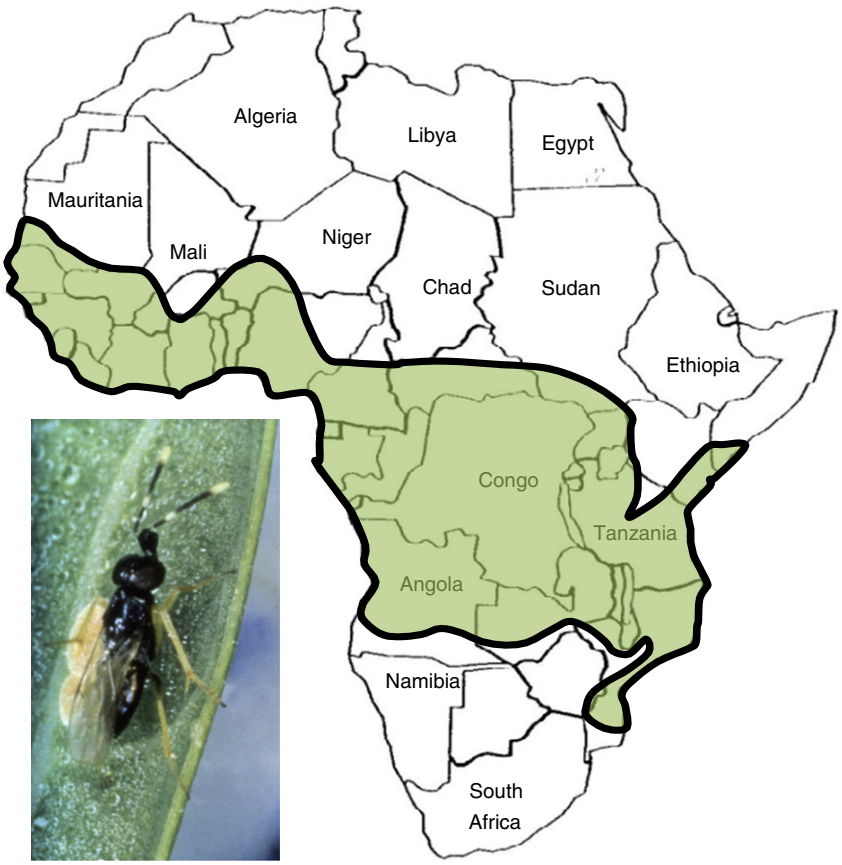

Figure 3 The extent of the cassava belt in Africa (shown green) with the cassava mealybug, *P. manihoti*, and its parasitoid *A. lopezi* inset.

palm. In contrast, the larval stage is not damaging and develops in compost or in the rotting trunks of dead palms. Following the discovery of the *Oryctes* nonoccluded virus in Malaysia in 1963, the first importation for biological control of rhinoceros beetle was made in Western Samoa in 1967. The result was a dramatic collapse of rhinoceros beetle populations due to effective horizontal spread of the virus across the Samoan islands by infected adult beetles (Huger, 2005). The success of this initial release led to an additional 17 importations throughout the Pacific islands, and in India and Tanzania, with establishment and significant suppression of the pest occurring each time (Hajek *et al.*, 2007; Huger, 2005). Life-history traits of entomopathogens that are linked with success are (1) a high level of specialization and virulence; (2) effective horizontal transmission, either by vectors or through possession of resistant stages that are able to persist for long periods in the environment; and (3) a very short replication time relative to the host generation time that allows them to cause high levels of host mortality (Hajek *et al.*, 2007; Shapiro-Ilan *et al.*, 2012).

Not all importation biological control programs against insect pests have proved to be successful; in many cases the imported natural enemies fail to establish, and those that do establish can also fail to provide the desired extent of suppression of the target insect pest. The BIOCAT database of importation biological control programs for insect pests, developed at the CABI UK Centre, lists more than 4700 releases of exotic parasitoids and predators (Greathead and Greathead, 1992; see also Clausen (1977) for further details), whereas Hajek *et al.* (2005) document 131 releases of exotic entomopathogens for the control of invasive insect and mite pests. From this documentation, on a global scale, the probability of establishment of a natural enemy following release has been greater for entomopathogens than for predators and parasitoids (**Table 1**), suggesting that, in small founder populations, predators and parasitoids may be more prone to allee effects than entomopathogens. The success of mate finding at low population densities can be an important constraint in the establishment of predators and parasitoids (Fauvergue, 2013) but does not limit the establishment of entomopathogens. Similarly, the probability of established natural enemies having a significant impact on the target pest has been greater for entomopathogens than for predators and parasitoids (**Table 1**). In this case, the greater success of entomopathogens is primarily due to the impacts of established viruses. Although the short replication time of viruses is considered to be of importance in generating high levels of host mortality, as noted above, viruses that are faster acting in killing their hosts may also limit the extent of horizontal transmission and consequently the propagation of viral epizootics (Sun *et al.*, 2006).

The variable success of importation biological control programs against insect pests over the past 100+ years clearly indicates that a more rigorous approach is needed in order to improve our understanding of the underlying ecological relationships that are central to importation biological control. Gurr *et al.* (2000) characterized the first half of this period of biological control importations as pursuing a 'shotgun' approach. It was anticipated that the extensive analyses of consumer-resource models by theoretical ecologists during the latter part of this period would provide a more informative framework for predicting success. Owing to a focus on stability and persistence (Briggs, 2009) rather than host suppression (Mills, 2000), however, these theoretical developments failed to lead to useful practical guidelines for importation biological control. One valuable pattern that did emerge from the historical record is that hemipteran pests are more likely to be suitable targets for successful population suppression than lepidopteran hosts, and there is some evidence that the explanation is linked to the numerical advantage of either a shorter generation time or gregarious development as a trait of the natural enemies involved (Mills, 2006).

There will always be a risk of unintended effects of deliberately imported exotic natural enemies on nontarget resident organisms occurring in the same geographic range as the target pest, and considerable attention has been paid to the identification and management of such risks in recent years. In addition to the potential for exotic natural enemies to directly impact nontarget organisms through trophic interactions, they could also cause indirect effects by disrupting other members of resident food webs in regions where they become established. A few historical importations, such as the misguided use of cane toads, *Rhinella marinus*, for the control of beetles in sugarcane fields and of the small Indian mongoose, *Herpestes auropunctatus*, for the control of rats, have played an inordinate role in fueling concerns about the irreversible and negative consequences of importation biological control. In recognizing the possibility for nontarget effects of imported natural enemies, most national plant protection organizations currently imposed regulatory requirements on the importation of exotic natural enemies, and procedures for minimizing the risk of direct effects on nontarget organisms are continually being improved (Barratt *et al.*, 2010). The Convention on Biological Diversity has also recently introduced some principles that govern access to genetic resources and the sharing of benefits arising from them (Cock *et al.*, 2010). The application of these

Table 1 The success of natural enemies used in importation biological control of insect pests

Natural enemy group	*Rate of establishment (n)*	*Rate of impact (n)*	*Overall rate of success (n)*
Predators and parasitoids	35.0% (2112)	41.4% (739)	14.5% (2112)
Entomopathogens	65.2% (69)	91.1% (45)	59.4% (69)

Notes: As estimated by the single best outcome approach to the bias caused by repeat introductions of the same natural enemy species in different geographic locations (see Mills (1994) for details).

principles has led to complex regulations that have already made the export of natural enemies from a number of countries almost impossible, and a more centralized regulatory framework will need to be developed if importation biological control is to be valued as a component of the future security of food production systems (Coutinot *et al.*, 2013).

Conservation Biological Control

In situations where natural biological control fails to provide sufficient suppression of an insect pest, the activity of resident natural enemies (indigenous or deliberately established) can be enhanced by human interventions that are known as conservation biological control. These interventions are based on the simple concept that, if the favorability of the environment for the resident natural enemies can be improved, it will lead to more effective suppression of the pest. However, as environmental favorability can be influenced by a wide variety of factors, discovering and manipulating the key limitation for the resident natural enemies in a particular agricultural environment can be challenging. Two more general aspects of conservation biological control that have shown promise more broadly in agricultural environments are habitat manipulation to favor natural enemies over insect pests and the protection of natural enemies from the harmful effects of pesticides.

Although habitat manipulation for conservation biological control has become the most extensively discussed topic in biological control (Bianchi *et al.*, 2006), it remains one of the least well understood and has yet to be widely adopted. The general concept is that local habitat manipulation to increase vegetation diversity through use of polycultures, cover crops, or the planting of noncrop habitats adjacent to crop fields can help to restore the limiting resources that predators and parasitoids experience in a crop monoculture, a concept that is deeply seated as one of the central tenets of agroecology (Altieri, 1999). Vegetation diversity influences predators and parasitoids by providing them with essential resources such as shelter and overwintering sites, alternative prey or hosts, and nectar and pollen as adult food sources. Cover crops can provide shelter and alternative prey for generalist predators, whereas mixed plantings of adjacent noncrop vegetation can provide valuable overwintering sites to facilitate rapid recolonization of fields in spring. Adjacent noncrop vegetation can also provide access to sources of alternative prey and hosts, and of floral resources to promote biological control during the cropping season (Landis *et al.*, 2012). The plant species to be used for habitat manipulation must be selected very carefully to ensure that they support natural enemies rather than insect pests or other antagonists. Native plants are favored over exotics as a result of their local adaptation and potential to contribute simultaneously to multiple ecosystem services. In addition, as the surrounding landscape is the source of natural enemies that can respond to local habitat manipulation, it also has an important influence on conservation biological control (Tscharntke *et al.*, 2005). The value of local habitat manipulation is expected to be greatest in landscapes of intermediate complexity, because complex landscapes should already provide a large community of natural enemies and supporting resources, whereas highly disturbed and simplified landscapes are unlikely to have a sufficient pool of natural enemies to be able to respond. Although there is some evidence that specialist natural enemies are more likely to respond to local habitat manipulation than generalists, the interplay between landscape complexity and local habitat manipulation seems likely to be system-specific and to depend on the biology and dispersal capabilities of different taxa of natural enemies.

One of the best examples of local habitat manipulation for the conservation of biological control in agriculture involves the planting of strips of floral resources in lettuce fields in California to enhance the abundance and activity of syrphid predators for suppression of the lettuce aphid, *Nasonovia ribisnigri*, an exotic insect pest first discovered in the state in 1998 (Tillman *et al.*, 2012). The lettuce aphid can form dense colonies on inner leaves of head lettuce where they are well protected from contact insecticides and many of the predators and parasitoids that are frequently associated with other aphid species. However, syrphid larvae were found to be the most important natural enemies of lettuce aphid in the Central Coast region where approximately 60% of the lettuce consumed in the United States is grown. This led organic lettuce growers to plant strips of sweet alyssum, *Lobularia maritima*, at intervals throughout their fields to provide a consistent supply of both nectar and pollen to a group of resident syrphid species that included *Allograpta obliqua*, *Platycheirus stegnus*, *Sphaerophoria sulphuripes*, and *Toxomerus marginatus*. Successful management of an invasive insect pest by a group of indigenous natural enemies is unusual, but the lettuce aphid provides an excellent example of local habitat manipulation that targeted the resource limitation of a specific taxon of natural enemies in a landscape of intermediate complexity. More generally, however, attempts to use floral strips to enhance biological control in agricultural crops have met with mixed results, indicating that it is not a universally applicable tactic for conservation biological control. Other examples of local habitat manipulation include the use of beetle banks, raised berms of tussock grass that provide suitable overwintering habitat-islands for generalist predators such as Carabidae, Staphlinidae, and Linyphiidae, within cereal fields in the UK (Tillman *et al.*, 2012), and the use of perimeter plantings that support alternative and overwintering hosts of insect parasitoids of leafrollers in fruit orchards in Washington (Unruh *et al.*, 2012). More generally, however, levels of adoption of strip or perimeter plantings to enhance biological control have been much lower than among organic lettuce growers in California, suggesting a need to better understand and predict when local habitat manipulation can be effective in conservation biological control.

Ever since the initial discovery of the insecticidal properties of dichlorodiphenyltrichloroethane in 1939 and the subsequent development of a broad range of synthetic insecticides as universal tools for the management of insect pests, the potential for disruption of natural biological control has been widely appreciated (Dutcher, 2007). The resurgence of target insect pests, and the replacement of initial targets by secondary insect pests as phenomena that result from the release of insect pests from natural biological control, have long been observed even when newer classes of reduced-risk pesticides such as neonicotinoids and spinosyns are used. Avoidance of pesticide-induced insect outbreaks can be achieved through

either physiological or ecological selectivity of the pesticides used in agricultural production. Physiological selectivity results from the differential susceptibility of insect species to a pesticide and can be greatly influenced by the mode of action of the pesticide. For example, the mode of action of many of the older classes of insecticides, such as organophosphates, carbamates, and pyrethroids, confers broad-spectrum activity such that they have lethal effects on a wide range of predators and parasitoids. For the newer classes of pesticides, the effects on natural enemies may still be lethal in some cases, but sublethal effects that reduce life-history performance are both more frequent and equally disruptive (Desneux *et al.*, 2007). In this regard, the International Organisation for Biological and Integrated Control Working Group on Pesticides and Beneficial Organisms has documented the selectivity of approximately 140 pesticides (acaricides, fungicides, herbicides, and insecticides) for a consistent set of 13 predator and parasitoid species using standardized bioassay methods (Jansen and Vogt, 2013). In contrast to physiological selectivity, ecological selectivity results from the differential exposure of insect species to pesticides (Hull and Beers, 1985). The most obvious approach to reducing the exposure of natural enemies to pesticides is through a reduction in the frequency or dose of pesticide applications. Lower dosages of pesticides frequently provide adequate levels of insect pest suppression, but unfortunately there is little evidence as to whether this typically results from conservation of natural enemies or from the lower dosages being as effective as higher dosages against the insect pests. Another approach to ecological selectivity is to choose pesticides with shorter persistence intervals, such that the natural enemies that are killed by a local application can be replaced more rapidly through recolonization from the surrounding landscape. More complex approaches include modification of either the timing or spatial placement of a pesticide application to ensure that natural enemies experience a refuge from exposure. For example, timing applications to avoid flight periods of adult predators and parasitoids, and either spot spraying or treatment of alternate rows or strips within a field, can provide suitable refuges for the persistence of natural enemies within an agricultural crop.

An extensive study of the management of sweet potato whitefly, *Bemisia tabaci*, in cotton in Arizona provides an interesting example of selective pesticide use and the conservation of biological control (Naranjo and Ellsworth, 2009a). An outbreak of the invasive B-biotype of *B. tabaci* in Arizona in 1992 devastated the cotton industry in the region and led to intensified use of broad-spectrum insecticides that included pyrethroids together with endosulfan and carbamates. However, between 1992 and 2007 Arizona cotton growers were able to reduce the number of foliar sprays from more than eight to just over one per year. There were three significant changes to the pest-management program over this period: (1) the introduction of two IGRs (pyriproxyfen and buprofezin) to replace pyrethroids for the suppression of *B. tabaci* in the mid-1990s; (2) the widespread adoption of transgenic Bt cotton for control of pink bollworm, *Pectinophora gossypiella*, by 2006; and (3) the introduction of flonicamid (with a new selective mode of action) to replace acephate for control of lygus bugs, *Lygus hesperus*, in 2007. Through a series of carefully designed field experiments, Naranjo *et al.* (2004) demonstrated the selectivity of the IGRs in comparison to conventional rotations of broad-spectrum insecticides in conserving the predatory arthropod community and in maintaining a greater ratio of predator to prey abundance (a measure of biological control potential) in cotton fields. In addition, using demographic life tables to analyze mortality in field populations of *B. tabaci* exposed to a series of different insecticide treatments (**Figure 4**; Naranjo and Ellsworth, 2009b) subsequently showed that insecticides typically replace the mortality caused by predation in the short term, and that the selectivity of the insecticides differentially influences the conservation of predation in the longer term.

Augmentative Biological Control

Augmentation is an approach to biological control when there are not enough resident natural enemies present in a specific local area, such as an agricultural field, to be able to suppress the abundance of an insect pest. The notion is that by deliberately releasing mass-reared individuals of one or more species of natural enemy, adequate suppression of the pest can be achieved either in the short term or for the whole growing season. A more rapid effect requires the release of large numbers of natural enemies to inundate the local area and suppress the abundance of an insect pest within a single generation. Thus inundation represents the use of natural enemies as biological insecticides without any expectation of longer-term effects from the turnover of natural enemy generations. In contrast, a season-long effect can result from the inoculation of smaller numbers early in the season with the subsequent turnover of natural enemy generations providing sufficient insect pest suppression throughout the cropping season. In reality, inoculation and inundation represent the two extremes of a continuum of augmentative biological control with intermediate scenarios occurring in many cases. One key assumption of augmentative biological control is that insect pest suppression is limited only by a lack of abundance of natural enemies in the target crop. This may not always be the case, however, as mass-reared generalist natural enemies may be unable to suppress populations of insect pests that are either less preferred components of their diet or that occur in habitats or microclimates to which they are poorly adapted. Similarly, augmentative releases of natural enemies may not be effective in domesticated crops that provide either spatial or structural refuges from natural enemy attack as in the case of the olive fruit fly discussed above.

For augmentation to be a commercially-viable approach to biological control, firstly, it is necessary to have a sufficient supply of mass-reared natural enemies available for use at specific, yet limited, times during the growing season. Secondly, the natural enemies must be of consistent high quality to ensure effectiveness, they must be easy to use to encourage adoption, and they must be produced at a cost that is attractive to the end user. The mass-rearing of natural enemies for augmentative biological control is conducted by state-funded and commercial natural-enemy producers who sell a range of different species for use in the management of insect pests. van Lenteren (2012) lists 230 species of predators and parasitoids, and Kabaluk *et al.* (2010) document the broad range of

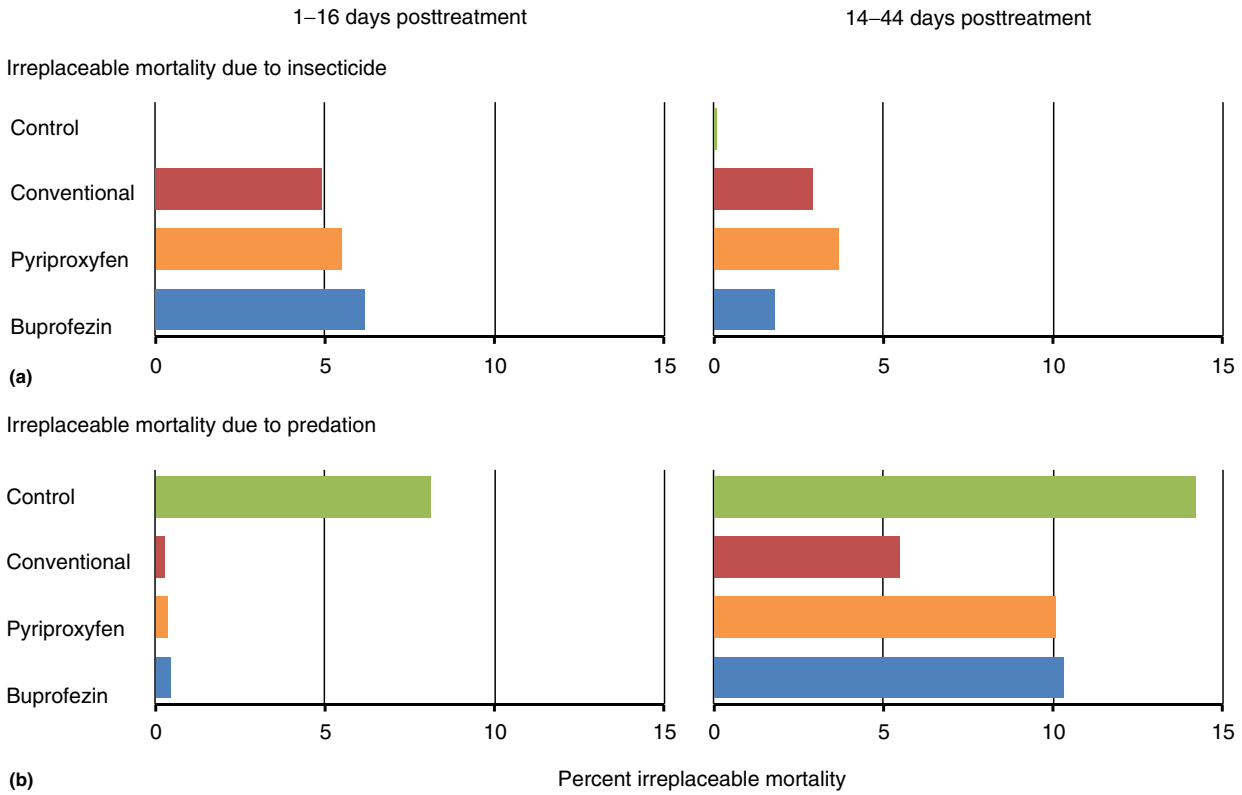

Figure 4 The irreplaceable mortality of *B. tabaci* in Arizona cotton fields. Whitefly mortality from predation was higher (8%) in the untreated control than from any of the insecticides (5–6%) in the treated plots immediately after insecticide applications (days 1–16). Two to six weeks later, mortality from the insecticides was low (2–4%) in the treated plots, and mortality from predation was high (14%) in the untreated control , but was also higher (10%) in the IGR-treated plots than in the conventionally treated plots (5%). Redrawn from Naranjo, S.E., Ellsworth, P.C., Hagler, J.R., 2004. Conservation of natural enemies in cotton: Role of insect growth regulators in management of *Bemisia tabaci*. Biological Control 30, 52–72.

microbial pesticides that are used globally for the augmentative biological control of arthropod pests.

Owing to a greater potential for reducing costs through improved methods of production, storage, and application, entomopathogens have been used more frequently than predators and parasitoids for inundative biological control (Shapiro-Ilan *et al.*, 2012). The narrow host-range of many entomopathogens reduces the potential risk of microbial insecticides to human health and to nontarget organisms, and their mass production is facilitated by culturing in liquid or solid fermentation. An interesting example of inundative biological control with an entomopathogen is the use of a host-specific nucleopolyhedrovirus (AgMNPV) for management of the velvetbean caterpillar, *Anticarsia gemmatalis*, in soybean production for more than 20 years in Brazil. The baculovirus was first isolated in the 1970s, and a small pilot program from 1980–82 demonstrated the tremendous potential of a viral insecticide for the management of velvetbean caterpillar in farmer's fields. The success of the pilot program led to a rapid increase in implementation from 2000 ha in 1982/83 to nearly 1.4 million ha or 10% of the total area of soybean production by 1998/99 (**Figure 5**). Production of the virus was initially based on harvesting diseased velvetbean caterpillars from virus-treated soybean fields, which were used initially as a crude solution and from 1986 as a wettable powder formulation. Commercialization of field production of the virus by private companies resulted in a peak harvest of approximately 45 tons of AgMNPV-infected caterpillars in 2003/04, sufficient to treat 2 million ha of soybean. However, the intensification of field production was associated with a reduction in the quality of the viral insecticide, and commercial laboratory production of a higher-quality product COOPERVIRUS PM began in 2004. Despite these successive improvements in virus production, the large-scale adoption of no-tillage planting and multiple cropping systems has led to significant changes in the insect pest complex associated with soybean production in Brazil and to the replacement of the viral insecticide program with renewed use of low-cost conventional insecticides (Panizzi, 2013). Nonetheless, the development of AgMNPV for inundative biological control of velvetbean caterpillar in soybean fields in Brazil represents a uniquely successful program, and one that involved the most extensive use of an entomopathogen for the biological control of an insect pest in a single crop. Its success can be attributed to a combination of high virulence and effective horizontal transmission of the virus, substantial tolerance of soybean to defoliation, lack of resistance in the velvetbean caterpillar, and efficient field-production of the virus by farmer cooperatives at low cost. Other viral insecticide programs, such as that for codling moth, *Cydia pomonella*, have

Assessment of the application of baculoviruses for control of Lepidoptera. Annual Review of Entomology 44, 257–289 and Moscardi, F., de Souza, M.L., de Castro, M.E.B., Moscardi, M.L., Szewczyk, B., 2011. Baculovirus pesticides: Present state and future perspectives. In: Ahmad, I., Ahmad, F., Pichtel, J. (Eds.), Microbes and Microbial Technology: Agricultural and Environmental Applications. New York, NY: Springer Science, pp. 415–445.

also been successful, although the development of resistance to the host-specific granulovirus CpGV after more than 20 years of use may pose a severe limitation to its continued use in Western Europe (Shapiro-Ilan *et al.*, 2012).

In contrast to inundative biological control, predators and parasitoids have been used more frequently than entomopathogens for inoculative biological control. Inoculation is very similar to importation as an approach to biological control, although it does not require the persistence of the natural enemy between cropping seasons. Nonetheless, the natural enemy must have a greater population growth rate than the target insect pest, must be well adapted to the habitat and microclimate in which it is used, and must be released into the crop early in the season to provide a sufficient ratio of natural enemy to insect pest individuals to ensure effective season-long suppression. Inoculative biological control has been used with greater success in enclosed greenhouse crops than in open field crops, with control of the greenhouse whitefly, *Trialeurodes vaporariorum*, by inoculative releases of the parasitoid *Encarsia formosa* being the best-known example (Hoddle *et al.*, 1998). This parasitoid was first mass produced for use in glasshouses in England in 1927 and has since become widely used for biological control of greenhouse whiteflies in tomatoes and cucumbers in many parts of the world. The parasitoid is typically mass produced by parasitizing whitefly nymphs on tobacco plants, and successful inoculative releases of parasitized nymphs early in the cropping season have been achieved using one of three methods. The pest-in-first method requires the deliberate release of whiteflies first, before release of *E. formosa*, to ensure that hosts are present in the crop for the parasitoids to colonize. The dribble method is based on regular releases of a low rate of parasitoids from the date of planting until parasitized nymphs are first found in the crop, and the banker plant method requires the introduction of previously grown plants that support breeding colonies of whiteflies and parasitoids. The effectiveness of greenhouse whitefly suppression is often monitored from levels of contamination of the crop by honeydew produced by the whiteflies and the sooty molds that grow on the honeydew. The success of inoculative biological control by *E. formosa* can be compromised if the quality of the host plants for greenhouse whitefly is too high, as in the case of beef versus round tomatoes, or if greenhouse temperatures fall much below 18 °C. For vegetable crops other than tomato and cucumber, and for greenhouse ornamentals, inoculative releases of *E. formosa* are generally not sufficient to provide season-long suppression of greenhouse whitefly, although control may still be achieved through inundative releases of *E. formosa* throughout the cropping season.

Future Directions

Reducing crop losses from insect pests is becoming of increasing importance as we seek solutions to the challenge of meeting the food security needs of a growing world population. For biological control to play a more pivotal role in the sustainable management of insect pests in agricultural production in the future, two developments will be needed.

First, one needs to become more effective in predicting when and where biological control can be most successfully implemented. As noted earlier, not every insect pest problem will have an available biological control solution. Better recognition of this limitation, and greater focus on problems where biological control is most likely to succeed would help to elevate the status of biological control in the minds of farmers and pest control practitioners. A variety of new research tools and directions are now available that provide valuable opportunities for future improvement in the success of implementing biological control solutions for insect pests

(Gurr and Kvedaras, 2010; Mills and Kean, 2010; Shapiro-Ilan *et al.*, 2012).

The globalization of trade and travel will continue to provide suitable pathways for the accidental introduction of exotic insect pests to areas of agricultural production in all parts of the world. Thus we can expect an ever-increasing need to consider importation biological control as a low risk option for the sustainable management of what could otherwise become a devastating problem that could threaten the stability of food production systems on a large geographic scale as occurred when the cassava mealybug was first discovered in Africa in the early 1970s. To be well prepared for such events, it will be necessary to resolve the constraints currently imposed by the Convention on Biological Diversity, and to be better able to predict and to improve on the probability for future successes. New research tools and approaches that have been developed in recent years offer exciting new directions for the improvement of successes in importation biological control. For example, prioritizing exotic insect pests for importation biological control and selecting effective natural enemies could be improved through greater use of molecular tools that allow a more rigorous approach for the identification of genetically distinct populations of invasive insect pests and their natural enemies, and for tracing the geographic origins of exotic invasions (Roderick and Navajas, 2003). In addition, the combined use of environmental niche models to facilitate climatic matching between regions of origin and invasion for imported natural enemies (Ulrichs and Hopper, 2008) and demographic models to facilitate the selection of effective natural enemies (Mills, 2005) could also lead to more predictable outcomes for importation biological control.

Current estimates of the extent of use of mass-produced natural enemies suggest that they may represent up to 5% of the global synthetic pesticide market (Jaronski, 2012; van Lenteren, 2012), with arthropod natural enemies being almost totally confined to use in greenhouse crops, and microbial pesticides being used in all cropping environments. The single most important factor limiting the more widespread adoption of augmentative biological control is cost effectiveness. The technical effectiveness of these natural enemy products is seldom in question, as was very clear to soybean farmers in Brazil when the viral insecticide for velvetbean caterpillar was first introduced (Moscardi, 1999); but the cost, if greater than the market can bear, could continue to be a limitation. Thus, the greater potential to reduce the costs of production of microbial versus arthropod products provides a clear opportunity and direction for the future expansion of augmentative biological control.

Second, and of equal importance, is the need for a greater emphasis on improved awareness of the value and potential of biological control. Whereas the successful outcome of a deliberate importation of an exotic natural enemy or an application of a microbial insecticide can provide a dramatic visual illustration of the tremendous value of natural enemies in the management of insect pests, it is far less easy to appreciate and value the contributions of natural enemies that result from either natural or conservation biological control. These contributions are much more difficult for farmers and pest control practitioners to visualize and can even be challenging to document from a research perspective. As noted in the Millenium Ecosystem Assessment (Sarukhán and Whyte, 2005) "In many agricultural areas, pest control provided by natural enemies has been replaced by pesticides." The reversal of this paradigm also provides one of the best opportunities to increase adoption of conservation biological control, as evidenced by the very successful program for insect pest management developed for rice production in Asia (Gallagher *et al.*, 2005). An important component of this particular program was the introduction of farmer field schools as a means to increase the awareness of farmers about the advantages of biological control (van den Berg and Jiggins, 2007). Other forms of complementary education and extension of information may be more appropriate for other crops and regions., It is clear, however, that a greater level of adoption of conservation biological control is unlikely to occur until its value can be elevated in the decision making of farmers and pest-control practitioners. In some cases, this may require strategies to incentivize farmers to change from the current market-driven model for decision making to one that considers the longer-term stewardship of agricultural resources and the environmental benefits experienced by the broader community.

Glossary

Antagonist The relationship between two species of organisms in which one individual adversely affects the other, as in competition; the inhibition of the growth of one type of organism by a different type that is competing for the same ecological niche.

Biocides A chemical or biological agent, such as a pesticide or herbicide, that is capable of destroying living organisms.

Biological control (biocontrol) Control of pests or pathogens by disrupting their ecological status, by the release of organisms that are natural predators or parasites.

Competitive exclusion An ecological principle that predicts that species that compete for the same resources cannot coexist when all factors are constant.

Disease suppressive A soil where the incidence of disease that develops on plants grown in that soil is less than that which develops on plants grown in other soils under similar conditions.

Endophyte Organisms that live within a plant for at least part of its life without causing apparent disease.

Inoculant Agricultural amendments that use beneficial, living microbes to promote plant health.

Pathogen A disease-causing organism or entity such as a bacterium, fungus, protozoan, or virus.

Pest An organism deemed detrimental to human concerns.

Pesticides Substances intended for preventing, destroying, repelling, or mitigating any pest.

Phytoalexins Antimicrobial substances that are synthesized *de novo* by plants and that accumulate rapidly at sites of pathogen infection. They tend to be broad-spectrum antibiotics that are key mechanisms in plant disease resistance.

Phytoanticipins These are antibiotic compounds similar to phytoalexins but they are always present in the plants. In many cases, they are stored as nontoxic compounds which on infection become activated by either the pathogen or the plant into the antibiotic structural state.

Rhizosphere The narrow region of soil that is directly influenced by root secretions and associated soil microorganisms.

Transgenic plant A plant whose DNA has been modified by adding a gene or genes from another individual or species, using advanced biotechnological techniques. The aim is usually to introduce a trait into the species, which is not normally there.

Concepts of Biocontrol Are Driven by an Ecological Balance

Biological control (BC) is an integral function of every ecological system that exists on this planet. Development and maintenance of an ecosystem requires mechanisms that regulate the balance between a host and its pest/pathogen populations. Any disruption in the system imperils the survival of both the host and pests/pathogens. Human attempts to rebalance an ecosystem by introducing living agents, their genes, or biochemical products to shift the balance in favor of the host are called BC. In its earliest phases of development BC focused on managing animals, insects, and weed species that became pests in ecological or agricultural systems (Howarth, 1991). In Australia, exploding populations of invasive species, such as rabbits and the prickly pear cactus, were successfully controlled by introducing pests from their native habitats. Control using such natural enemies is termed classical BC and it remains a major component of pest management on a global scale. Van Driesche *et al.* (2010) reviewed 70 cases of classical BC, which targeted 21 insect pests and 49 invasive plants. All projects proved to be successful in controlling the target pests and all benefitted biodiversity, protection of the products being damaged, and the ecosystem. Today, the concepts derived from classical BC are applied globally to protect greenhouse crops from insect pests. Classical BC of insect pests mostly involved finding an insect from its native habitat that could act as a control agent. Classical control for plant diseases, which are mostly caused by microorganisms, would require finding control agents that are also microorganisms (or their genes or gene products). This approach, however, has not been very successful, except perhaps for mycoparasites. A major reason is that in most countries the regulatory agencies automatically classify a microbe intended for pest control as a pesticide and their importation and deployment would be subject to approval under all pesticide laws. Until now insects intended or used for BC have not been regulated as pesticides but this may also change.

The United Nations estimates a world population of approximately 9 billion by 2050; an increase of almost 25% at the time of writing this article. To feed this population 70–100% more food will be needed. Meanwhile, preharvest losses due to pathogens, pests, and weeds account for anywhere from 20% to 40% of the world's agricultural productivity. Reducing such losses to plant diseases and pests would help meet the increased food production targets. However, this will require an increased use of pesticides at a time when society already demands reductions in agrochemical contamination of food, water, and the ecosystem. Societal pressures are boosting markets for biopesticides and transgenic crops. Drogui and Lafrance (2012) suggest that the rapid uptake of genetically modified crops carrying resistance to insects by virtue of

 doi:10.1016/B978-0-444-52512-3.00177-7

proteins derived from *Bacillus thuringiensis* (Bt) can be viewed as the pivotal step in the development of modern agriculture as it induced a fundamental change in the use of pesticides. Although this has allowed a paradigm shift in the administration of pest control, it can also be viewed as a form of breeding for disease resistance which is certainly not a new agricultural concept. Studies on benefits derived from the implementation of Bt cotton in China from 1990 to 2010 show that the reductions in the use of chemical insecticides resulted in marked increases in arthropod predators that provided additional biocontrol services. These not only benefitted cotton but also the neighboring crops, such as maize, peanut, and soybean. It is expected that similar data from other ecosystems where ecological agricultural is practiced will greatly favor the growth in biocontrol technologies.

The evolution of commercial biological products and factors that contribute to the successes or failures of companies dealing with such products are complex (Ravensberg, 2011). Despite great turbulences in the market, the prospects for the growth of biocontrol products are universally predicted to increase at a rate of approximately 7% per year. In part, this is because the costs to get a biological product to market are less than US$10 million dollars, whereas development costs for chemical pesticides are closer to US$200 million. Currently, biological insect control products dominate the market and sales of control products for plant pathogens are less advanced. This is expected to change as pathogen management become a target for multinational companies. In 2012, Bayer Crop Science, one of the largest producers of chemical pesticides purchased AgraQuest, a world leader in BC products. The entrance of companies such as Bayer into the biocontrol business will provide a more stable platform for financial and human resources which ensures that products are widely marketed and supported, a factor that has been greatly missing in the field of BC.

Benefits and Limitations of Biocontrol

One of the major highlights of using biocontrol in agriculture is its specificity for a particular species or taxonomic group; also considered by some to be a limitation as growers are accustomed to pesticides that control a wide spectrum of pathogens. The narrow spectrum of activity makes biocontrol ideal for integrated pest management systems where other beneficial agents are being utilized. BC is ideal for organic production systems and is compatible with pollinators (bees primarily) which are very sensitive to pesticides. Biocontrol products do not leave harmful residues so agricultural produce can be marketed within a short time after treatment. The products are considered safe for applicators and reentry to treated sites is either not limited or can be as short as a few hours. Biocontrol agents are considered to be more resilient to the development of pest resistance than traditional chemical control. The major weakness of biocontrol is that efficacy is greatly influenced by environmental factors, and they are rarely as effective as chemical pesticides because of this. Control activity is not as rapid as with chemicals. Considerably more knowledge is required in the manufacture and use of these products and formulations than with traditional chemical pesticides, with shelf-life and storage conditions significantly affecting the utility of the product.

The list of BC agents and their products that are registered for use commercially is expanding at a tremendous rate. The references and web sites where products available to growers can be located are provided. Information is also available from specific publications that detail the biocontrol products currently marketed (McSpadden Gardener and Fravel, 2002; Fravel, 2005; Kabaluk *et al.*, 2010; Ravensberg, 2011; Glare *et al.*, 2012; Rana, 2012).

A Biological Control Model in Natural Systems: Endophytes

Endophytic microorganisms, primarily bacteria and fungi, are found inhabiting the interior of plants where they can contribute to the host's growth without causing disease. Endophytes are increasingly being recognized as organisms with enormous potential for use in management of plant health as they can overcome the major limitation in effective BC: biologically relevant delivery and robust establishment due to niche adaptation and shelter from microbial competition and environmental influences. These microbes are protected from the outside environment as they exist in the internal tissues of the plant where they form a diversity of relationships ranging from symbiotic to almost pathogenic (Ryan *et al.*, 2008). Although many endophytes are likely transmitted from generation to generation through seeds or vegetative organs, it is possible to introduce new endophytes to plants through wounds or through seed inoculation, where they can create systemic infection and persist for the lifespan of the plant. Endophytic microorganisms have been shown to control numerous plant pathogens, insects, and nematodes and to exert growth-promoting functions that make plants less prone to infections.

The potential of endophytes to impact plant health and productivity, as well as ecosystem integrity, is best illustrated by the relationship between perennial ryegrass and its fungal endophytes (Kuldau and Bacon, 2008). Perennial ryegrass is grown worldwide as feed for livestock and is an integral component of most pastures. Ryegrass is usually infected with the fungal endophyte *Neotyphodium lolii* formerly known as *Acremonium lolii*. The fungus depends on the plant for its survival and spread and; in turn, it confers numerous benefits to the plant that include increased growth, photosynthetic capability, nitrogen assimilation, and mineral uptake. Infected plants are taller, are more vigorous, have a greater capacity to resist harsh environmental conditions, such as drought, nutrient deficiencies, soil acidity, etc. Often they completely displace noninfected plants and eventually the ecosystem contains only plants with endophytes. Not all grasses tolerate colonization in an equal manner.

Most importantly the fungus confers host resistance to insect and animal herbivores by virtue of its ability to produce a number of toxic alkaloid metabolites generally known as tremallogens (Kuldau and Bacon, 2008). Of the many known and unknown compounds produced, several act synergistically to provide broad-spectrum protection to multiple pests. These compounds have antifeeding activity but, if ingested, they make the animals sick with a disease known as ryegrass

staggers. Similar alkaloids can be found in grain infected by *Claviceps* fungi (of which *N. lolii* is a member) that induce a human disease known as ergotism or St Anthony's Fire which caused hundreds of thousands of deaths in the Middle Ages. *Neotyphodium* endophytes confer resistance to some 45 species of insects (Kuldau and Bacon, 2008) and at least two plant-parasitic nematodes. The fungus also stimulates the accumulation of the phytoalexin resveratrol which has potent antifungal activity. This phytochemical may account for some of the resistance seen with infected grasses against *Pythium* disease, dollar spot, some rust and leaf spot diseases. There is also suggestion that the presence of the endophyte induces a systemic acquired resistance (SAR) mechanism, allowing plants to respond more quickly to parasitic attack from a diverse group of plant pathogens (Kuldau and Bacon, 2008).

Endophyte-infested grasses were previously sold for lawn use as a means of reducing insect damage and watering but they did not come into widespread use because of the accumulation of toxins. Since then, isolates that lack the capacity to produce toxins harmful to animals but still retain other desirable traits associated with disease suppression and plant growth promotion were identified and patented (USA patent 6,111,170) and are sold in New Zealand, Australia, USA, and South America as AR1TM and AR37TM in ryegrass and MaxQ in tall fescue. It is envisaged that not only will this benefit pasture maintenance, but once such seeds become widely planted populations of fungi that produce harmful toxins will be significantly reduced in the environment by competitive exclusion.

This example of improved endophyte delivery shows how seed transmission of beneficial microbes could become a very powerful technology. Such processes are likely ongoing in nature. Surface-sterilized husked seeds of rice have been found to contain 5 000 000 colony forming units of bacteria per gram (Ruiza *et al.*, 2011). Some of these seedborne bacteria fix nitrogen and protect against infection by the fungus *Curvularia* spp. Two isolates of these bacteria were potent root colonizers during seed germination, suggesting how they might colonize other parts of the plant. In a metagenomic analysis of the endophytic bacterial community that reside inside roots of field-grown rice, Sessitsch *et al.* (2012) found that the endophytes might be involved in the entire nitrogen cycle, including N_2-fixation, denitrification, and nitrification. The endophyte community comprised functions involved in plant growth promotion, improvement of plant stress resistance, biocontrol against pathogens, and bioremediation.

An example of the huge impact that endophytes could have in wide-scale agriculture is found in the implementation of sugarcane as a biofuel crop in Brazil. The success of the bioethanol industry is due to the development of production systems that allow this crop to be grown with minimum expense and little environmental impact. From inception, cultivars of sugarcane were selected and bred for minimum requirements of pesticides or fertilizers (Baldani *et al.*, 2002). Cultivars that performed well under such conditions were found to be harboring numerous bacterial species such as *Azospirillum*, *Herbaspirillum*, *Acetobacter*, *Klebsiella*, *Burkholderia*, and others. These bacteria not only helped to supply nutrients required for growth, but also provided protection to the roots from plant disease-causing agents. These beneficial plant–microbe relationships allow Brazilian sugarcane growers to use 70% less nitrogen fertilizer than sugarcane growers in the USA. The bacterial endophytes dramatically aid the plant's mineral nutrition, as well the plant's defense against pathogens. *Azospirillum* isolates improve growth of crops other than grasses including oilseed rape, tomato, pepper, etc. and significantly reduce disease symptoms or incidence of damping-off in chili caused by *Pythium*, or wilt pathogens such as *Verticillium dahliae* and *Fusarium oxysporum f.* sp. *lycopersici* and the bacterial pathogens *Clavibacter michiganensis* subsp. *michiganensis* (bacterial canker), *Xanthomonas campestris* pv. *vesicatoria* (bacterial spot), and *Pseudomonas syringae* pv. tomato.

Endophytes can be used as delivery vectors for genes from other biocontrol agents that provide plant protection. The *Bt* gene conferring CRY toxin production was cloned into several bacterial endophytes, such as *Xylaria*, in the hopes that it could help kill root worms. However, the biocontrol that resulted was not sufficiently effective due to the limited number of bacteria in the root environment. The endophytic nitrogen-fixing bacteria *Acetobacter* and *Herbaspirillum* were also used as potential models for gene delivery but as yet commercial products are not available. In another example, the antifungal endophytic fungus *Chaetomium globosum* has been genetically modified to express insecticidal lectins within rape, thus producing plants with both disease and aphid control capabilities (Qi *et al.*, 2011).

Management of Soilborne Pathogens Using Organic Amendments and Crop Rotations

Control of soilborne plant pathogens has been the most difficult aspect of plant protection. The most successful method of control available relies on plant resistance to a specific pathogen. When resistance is not available, fumigation with broad-spectrum biocides is usually employed but many such products are being removed from the market place. Adding pesticides to soil is difficult as a hectare of soil weighs approximately 2 million kg to a 15 cm depth and this requires adding large volumes of chemicals to reach toxic concentrations. Furthermore, due to the diversity of soil microorganisms chemicals are often rapidly degraded. The disease control strategy that has gained the most momentum is to alter both the microbial composition of bulk soil and the soil surrounding the root system known as the rhizosphere. Peter *et al.* (2009) characterize some of the processes being developed to manipulate the root-associated microbiome to improve plant health and productivity as 'rhizosphere engineering and management.' They detail case studies whereby plants or the microorganisms are genetically altered to enhance interactions that lead to expression of factors that bring about BC or improved root health. It is enticing to consider all soil treatment processes leading to either higher or lower disease incidences as a form of rhizosphere engineering and management.

Soils naturally resistant to the development of specific soilborne disease are termed 'disease suppressive.' Two classical types of suppressiveness have been identified and they will be dealt within another article. With 'general suppression,' the main factor altering disease outcomes is likely derived

from competition between the total soil microbiota and the pathogen for resources. This is not a transferable function between soils. 'Specific suppression,' however, is associated with specific antagonistic microorganisms, such as the fluorescent pseudomonads which interact with individual or select groups of pathogens. Suppressiveness can act either by keeping pathogen inoculum concentrations very low or, more commonly, keeping disease incidence low even though pathogens may be present at high levels. By adding suppressive soil to disease-conducive soils, suppressive traits can be transferred as the activity resides in microorganisms (Cook, 2007).

The most successful example of the creation of disease-suppressive soils known is actually a strategy where rotation is not used but is replaced with continuous cropping of a monoculture. The development of this technology is described in this book by Cook . Repeated cropping of wheat was shown to increase the populations of antibiotic producing fluorescent *Pseudomonads* on the roots resulting in significant reductions in the severity of take-all root disease of wheat and barley caused by the fungus *Gaeumannomyces graminis* var. *tritici*. Specific strains of *P. fluorescens* have subsequently been shown to be widely involved in suppression of other soilborne root diseases. Fluorescent pseudomonads have also been shown to suppress damping-off diseases caused by widespread and generalist pathogens such as *Pythium ultimum* (an Oomycete) or *Rhizoctonia solani* (a fungus) (Ligon *et al.*, 2000). Suppressive conditions in soils and substrates have been reported for a wide diversity of pathogens that cause wilts and root rots, including *Fusarium* spp., *Phytophthora* spp., *Thievilopsis*, *Plasmidophora*, *Streptomyces scabies* as well as for plant-parasitic nematodes. Identification of the biological properties contributing to disease-suppressive conditions have proven to be elusive for most systems except for the take-all disease of wheat. This model ecosystem can be considered a major breakthrough toward developing an ecologically based management technology for soilborne plant disease control. Establishing suppressive conditions provides a safe, effective, environmentally benign and cost-effective approach to managing crop diseases. Once the suppressive agents or their biological activities are known, DNA technologies based on polymerase chain reaction can be used to detect the trait and develop crop management technologies to keep suppressiveness in place or even improve its impact. Molecular technologies are now being applied to unravel factors and microbial communities impacting soils and crop health.

Traditional crop rotations were designed to withhold crops that are susceptible to a specific pathogen from agroecosystems for a sufficient time during which the pathogen populations decline to below crop loss disease thresholds. Cook (personnel communication) suggests that crop rotations of 2–3 years or longer provide sufficient time for the soil microbiota to reduce populations of a crop-specific soilborne pathogen to a level that is below the crop loss threshold, as long as the crop grown in rotation is unrelated to the primary crop. For some diseases, such as *Verticillium* wilt, this does not work well as resting structure of the fungus can survive for decades and they have the capacity to reproduce on a wide host range that includes weeds. The practice, however, does work for short-lived pathogens (Cook, 1988). For long-lived soilborne pathogens growing resistant cultivars induces the resting structures to germinate but infections do not lead the production of new inoculum and over a period of time the resting structures become depleted. Incorporating the residues of rotation crops induces the growth of a wide spectrum of microorganisms that have been shown to damage the resting structures of plant pathogenic fungal agents by numerous mechanisms (Bailey and Lazarovits, 2003). Application of organic amendments to soil has been shown to result in important changes in soil microbial communities which can reduce the impact of soilborne plant pathogens. Amendments may include animal and green manures (green crops plowed down), composts, agricultural by-products derived from food processing, such as molasses, meat and bone, soy meal, canola meal, fish and shrimp waste, etc. Applying organic amendments has been an integral part of agriculture since its inception, but now one is starting to understand how these treatments may alter populations of soilborne pathogens and their antagonists. Changes brought about by organic amendments can be considered as BC as the changes in the pathogen populations occur only after the products are metabolized by soil microorganisms. Accumulations of high levels of metabolic products such as ammonia, nitrous acid, volatile fatty acids including formic acid and acetic acid (vinegar), cyanide, etc. can be toxic to many pathogens and pests. Many of these products have been used for food preservation for millennia and are considered very safe. Whereas plant pathogens are often damaged or killed, most soil microorganisms increase in population by several log units. Some microorganisms known to be enriched include *Bacillus*, *Pseudomonas*, and *Trichoderma*, and they are known BC agents. The limitations for use of such technologies are the inherent variability of control achieved, high cost, limited quantities, and a lack of understanding of the processes that lead to disease control.

Numerous preplant strategies for the control of soilborne pathogens in various crop production systems have been shown to be effective. Mustard seed meal amendments were found to reduce pathogen populations and to even create disease-suppressive soils for a wide spectrum of root pathogens, including *Fusarium*, *Pythium*, *Rhizoctonia*, *Verticillium*, various plant-parasitic nematodes, and complex disease such as apple replant. Materials utilizing *Brassica* species or their seeds were commonly viewed as yielding disease control through the process of 'biofumigation,' i.e., the release of toxic products such as cyanide during residue decomposition. It is now known that specific elements of the soil biological community also contribute to disease or weed control. The modes of action likely vary from pathogen to pathogen and the source of the product can also modulate disease control efficacy.

Adding large quantities of organic matter to soil, wetting the soil, covering it with plastic and letting the microorganisms degrade the organic matter has been found to result in the formation of anaerobic conditions that reduce populations of a broad spectrum of soilborne plant pathogens and nematode pests. This control method, termed anaerobic soil disinfestation (ASD), is widely used in Japan where production sites are fairly small. The process is considered to act by numerous mechanisms including withdrawal of oxygen and production of volatile fatty acids. ASD has been consistently effective at suppressing a broad spectrum of soilborne plant pathogens

and has been used to control wilt and root diseases of high-value horticultural crops.

Nematode Control

Crop losses caused by plant-parasitic nematodes are estimated to exceed US$100 billion worldwide. The primary means of control has been the use of chemical fumigants but exciting new biocontrol technologies are being developed. *Pasteuria penetrans*, a bacterial parasite of nematodes, was discovered to be able to eradicate a wide spectrum of plant-parasitic nematodes and to bring about disease-suppressive conditions for such pests. The bacterium's spore has the appearance of a flying saucer and attaches itself to the nematodes' cuticle, penetrating through it on germination. Once inside, the bacterium divides rapidly until it fills the entire nematode cavity. The bacteria then start to produce spores that are released to infect other nematodes. *Pasteuria* is a biotroph, i.e., requires living tissues to grow. The discovery that these bacteria can be grown in nematode cell culture has allowed for large-scale production of the organism and their commercialization for agriculture. Pasteuria Bioscience, Inc., is commercializing this biological nematicide under the trade name Econem, which is currently registered for protection of turf. They are developing products to control all important nematode pests such as root-knot, soybean cyst nematode, and the reniform nematode. A patent has been granted for use of *Pasteuria* spores as a seed treatment. Syngenta acquired Pasteuria Bioscience Inc., in 2012 and intends to develop and commercialize this biocontrol products for nematodes worldwide. The first major product, a seed treatment for soybean cyst nematode, is expected to be launched in the USA in 2014. Along similar lines, MeloCon Biological Nematicide contains a naturally occurring fungus, *Paecilomyces lilacinus*, a highly effective parasite of all stages of development of common plant-parasitic nematodes, especially the eggs and infectious juveniles.

Induced Resistance

A plant's natural resistance to pest and pathogens will always be the best strategy for plant protection in agriculture. Plants have evolved many genes for disease resistance that negate the function of the pathogen's virulence factors. Pathogens, in turn, have evolved methods to overcome plant resistance genes, giving rise to new races that can cause disease. Introduction of new disease-resistant genes into crops by conventional breeding practices can take up to a decade, and in many cases genes for specific pathogens are not readily available. Although plants may become susceptible to new races of pathogen, they retain their resistance mechanisms. If one can activate these genes before attack then they confer resistance to the pathogen. Many of the mechanisms associated with the major plant disease defense response, called SAR, have been characterized. SAR has been shown to be activated in response to various biotic or abiotic triggers, including rhizobacteria, fungi, their products, and a number of chemical compounds. SAR activation can be measured by the expression of pathogenesis-related genes, production of defense-related enzymes, and accumulation of phytoalexins and phytoanticipins.

Biochemicals such as salicylic acid, methyl jasmonate, benzothiadiazole, or acibenzolar-*S*-methyl are potent activators of plant defense responses against certain pathogens and insects. For example, foliar application of methyl jasmonate (a volatile compound released from flowers and leaves) can trigger a plant's jasmonic acid pathway that, in *Arabidopsis*, significantly reduces disease development by necrotrophic fungi such as *Botrytis cinerea*, *Alternaria brassicicola*, and *Plectosphaerella cucumerina* (Pozo *et al.*, 2005). An extract from the giant knotweed *Reynoutria sachalinensis* has been commercialized under the trade name Regalia by Marone Bioinnovations. Regalia controls many important fungal and bacterial diseases, including powdery mildew, downy mildew, *Botrytis* gray mold, early blight, late blight, citrus canker, brown rot, bacterial leaf spot, target spot, gummy stem blight, and others. It is registered for use against soilborne pathogens such as *Pythium*, *Fusarium*, *Rhizoctonia*, and *Phytophthora* and was shown to improve root development and plant growth response with tomatoes, peppers, potatoes, strawberries, and others (http://www.marronebioinnovations.com/products/regalia/). A synthetically produced compound, acibenzolar-*S*-methyl, is sold by Syngenta Crop Protection as Actigard® or Blockade® and is registered with the US government's Environmental Protection Agency (EPA) as a plant defense activator. It is meant to be dissolved in water and applied as a foliar spray to preventatively control disease by triggering SAR.

Plants produce over 1000 volatile compounds naturally, some specifically in response to infection and pest attack. Many of these compounds activate plant defences not only in plants under attack but also in the neighboring plants. Interestingly, these volatiles can also function as signal molecules to predatory or parasitoid arthropods, informing them that prey may be present in large numbers. For example, methyl salicylates released by soybeans in response to aphid infestation act as strong attractants to lady beetles. Synthetic methyl salicylates have been successfully used for attracting beneficial insects to the field and constitute the active ingredient for PredaLure (AgBio, http://www.agbio-inc.com/predalure.html) a natural enemy attractant marketed for use in pest management. Kaplan (2012) details the complexities of using such mechanisms for insect control and the potential for wide-scale applications.

Transgenic Plants

The first commercially grown transgenic plants were virus-resistant tobacco and tomato grown in the early 1990s in China, followed in the USA by Calgene in 1996 with their delayed ripening Flavr Savr tomato (Collinge *et al.*, 2010). Since then, the total area planted to transgenic crops (in 2010) has grown to 365 million acres in 29 countries, planted by 15.4 million farmers; (http://www.isaaa.org/kc/cropbiotechupdate/pressrelease/2012/default.asp) an obvious case of commercial success. Interestingly, almost all of these commercially planted transgenic crops bear traits for herbicide tolerance for weed control and Bt resistance for insect control; very few were made for improved disease resistance. Indeed, with the exception of some virus-resistant transgenic plants, there are currently no commercially released transgenic plants

on the market for plant disease control; a situation that will likely change in time, as 2000 of the almost 16 000 field trials in the USA in the past 20 years are for disease resistance traits, suggesting there are crops either in the pipeline or on the shelf due to the high cost required for meeting regulatory approval (Collinge *et al.*, 2010). The restrictive regulations required to meet approval for products intended for export markets by all countries that may import the product has also acted as a constraint in the development of novel transgenic crops. Approval of the importation of virus-resistant papayas from Hawaii to Japan took in excess of 10 years.

Traditionally, classical breeding is used to enhance resistance by selecting optimal combinations of the plant's own genes. With transgenic techniques, also known as molecular breeding, selection of resistance genes can involve mutating or overexpressing alleles within the species, or it can additionally allow transfer of homologous genes from an unrelated plant species. Thus, research into the genetics and biochemistry of plant-pathogen signaling and resistance will increase the tool box for both the species being researched and other plant varieties as well.

Arabidopsis is the best understood plant species at the biochemical and genetic level. Although it has no agronomic value, it has proven to be a valuable resource for identifying genes and the mechanisms they control. For example, the entire biosynthetic pathway for benzylglucosinolate (a secondary metabolite involved in defense against generalist insects and pathogens) has been transferred from *Arabidopsis* to tobacco (Collinge *et al.*, 2010), with further work in potato expected to bestow resistance to *Phytophthora infestans* (late blight). The defense-signaling gene *NPR1* (nonexpressor of pathogen-resistance genes), which is necessary for induction of plant SAR in *Arabidopsis*, was stably transferred and overexpressed in tomato, wheat, carrots, and tobacco where it has increased the crop's ability to respond to and resist pathogen attack, without showing signs of compromised growth (Wally and Punja, 2010).

A divergent approach called pathogen-derived resistance transfers a pathogen's gene(s) into the plant genome to achieve disease immunity. This approach has resulted in the only commercially successful transgenic disease-resistant plants, which are immune to virus attack by virtue of their overexpression of genes for viral coat proteins (so the target virus cannot successfully unpack its nucleic acids and infect the plant) or gene constructs mimicking viral gene sequences, which trigger the plant's own gene-silencing mechanisms (RNA interferance (RNAi)). Transgenic virus-resistant plants have been grown commercially for over a decade in the USA, and even longer in China. The most famous commercially available example of this approach was showcased by the Hawaiian papaya industry, which was nearly wiped out by the papaya ringspot virus. In response to this catastrophic disease, the transgenic varieties SunUp and Rainbow were developed from the parent variety Sunset, by transferring the virus's own coat-protein gene to the plant's genome where it was overexpressed, thus blocking the virus's ability to undress and have its genes transcribed. These varieties of transgenic papaya currently enjoy over 70% of the acreage in Hawaii and are credited with saving the entire industry.

Additional attempts to protect plants from pathogens using transgenic technology include transfer of antimicrobial proteins from diverse sources, antibodies from animals (which are then termed 'plantibodies'), and mechanisms to interfere with pathogen virulence factors and communication. For example, transgenic expression of the antimicrobial peptide dermaseptin B1 from the South American tree frog *Phyllomedusa bicolor* has been shown to increase resistance to bacterial and fungal diseases, including late blight, dry rot, and pink rot, in addition to significantly extending the shelf-life of tubers (Osusky *et al.*, 2005). Plantibodies might be useful to tag particular pathogens for further antimicrobial targeting; this approach has been used successfully to deliver antifungal chitinase and defensin proteins specifically to *Fusarium* cell walls by generating antibody: antimicrobial gene fusions inserted into the genomes of *Arabidopsis* (which was then resistant to nine different species of *Fusarium*) and wheat (which was then resistant to *Fusarium* head blight) (Wally and Punja, 2010). Plants expressing large amounts of pectinase-inhibitory proteins dramatically inhibit the virulence of necrotrophic pathogens like *B. cinerea*, which secrete pectinases as a way to digest plant tissues and liberate nutrients for their absorption (Wally and Punja, 2010). Likewise, transgenic plants expressing enzymes that degrade bacterial communication signals (quorum sensing) can have enhanced resistance to pathogens, although this has not found commercial application yet.

Biological Amendments

Bacteria

Bacteria are among the most frequently used biocontrol agents to protect plants from diseases. Although bacterial agents have been used for several decades, it is generally thought that their potential is vastly underexplored. Bacteria reside on all plant parts in abundance and have direct and indirect plant growth-promoting capabilities. There are 10–100 times more bacteria living on the plant root than living in the soil mass. Bacteria live inside plant tissues and can be transmitted vertically through seed to the next generation. The search for bacterial biocontrol agents is in its infancy, however, with many labs developing screening criteria to use in high-throughput approaches for new agent isolation. Bacterial biocontrol agents are most frequently isolated from the root zone, but they can arise from any plant-associated environment, including the endosphere (inside the plant), phyllosphere (the surface of the leaf), and spermosphere (inside and around the germinating seed).

The most commonly proposed mechanisms by which bacteria control pathogens are niche competition with pathogens, production of inhibitory allelochemicals, and induction of plant resistance pathways (Compant *et al.*, 2005). To provide protection to crops, beneficial bacteria need to competitively colonize the plant tissue they are to protect. Bacteria use different mechanisms to effectively colonize the plant, including flagellar-driven motility, chemotaxis, and efficient utilization of nutrients in the environment. Common allelochemicals produced by biocontrol bacteria include antibiotics that directly inhibit pathogens, iron-capturing molecules that sequester this limiting nutrient, and secreted enzymes that lyse pathogenic cells.

Globally, bacteria represent 75% of the 3.5% of the agrichemical market that is represented by biocontrol (Glare *et al.*, 2012). In North America, the list of available bacterial biocontrol agents is growing continually as they are used more widely. That the majority of biocontrol agents are comprised of Gram-positive bacteria can perhaps be explained because these form spores which are more resistant to stress and are easier to store than are Gram-negative bacteria. Two widely used examples are Serenade (Bayer CropScience – Monheim, Germany), *B. subtilis*, and Sonata (Bayer CropScience – Monheim, Germany), *B. pumilus*. Both products protect a variety of crops from downy and powdery mildew, early and late blight, and brown rot. In addition to the dried *B. subtilis* spores found in Serenade, the fermentation conditions have been optimized to produce a profile of lipopeptides which improve biocontrol performance in the field and increase the spectrum of pathogens targeted.

Another important group of biocontrol bacteria are *Pseudomonas* species, which are robust plant colonizers, produce a variety of antibiotics, and are easy to culture (four are registered with the US EPA). Additionally, it is being recognized that combinations of bacteria may provide better crop outcomes than single strains. An example of this is the Biostacked soybean inoculant (Becker, Underwood – Ames, Iowa, USA), which contains the nodulating *Bradyrhizobium japonicum* and *B. subtilis* for growth promotion due to phytohormone production and disease suppression, primarily *Rhizoctonia* and *Fusarium*.

One of the earliest biocontrol products utilizing bacteria was *Agrobacterium radiobacter* K84 for control of the closely related bacterium *A. tumefaciens*, causative agent of crown gall in woody plants. By simply dipping the roots of plants in a cell suspension of *A. radiobacter* K84 before planting in an infested field, the crown gall is controlled. The biocontrol strain produces Agrocin-84, a molecule that mimics agrocinopine A, a nutrient source for bacteria inside galls. Agrocin-84 is imported into the pathogen cell by the same transporters used for agrocinopine A, whereupon it inhibits DNA replication and cell growth of the pathogen. For Agrocin-84 to work, the pathogen must require agrocinopine A for its growth. Thus, strains that do not utilize this opine during infection are insensitive to Agrocin-84. Many products containing *A. radiobacter* strains are commercially available for crown gall control. Members of the family Rhizobiaceae, containing the genera of *Rhizobium* and *Agrobacterium*, are common inoculants of legume plants. However, this genus is ubiquitous in soil and on nonlegume plants. There are some reports that Rhizobium spp. can act as biocontrol agents against soilborne pathogens and nematode pests, but they have not been seriously examined as potential biocontrol agents likely because they are viewed only as nitrogen fixers.

Although biocontrol bacteria need to be able to compete for colonization on the plant with native flora and pathogens, implicit in the name biopesticide is the need for reapplication as the biocontrol bacteria are not able to reside in the soil in large enough populations to provide disease control for years. Although improved fermentation conditions had led to increased product efficacy, genetic manipulation of the organisms provides a means to optimize activity and environmental survival. Owing to strict regulations and public perceptions of genetically modified organisms, no commercially available product is genetically modified. However, directed evolution of biocontrol bacteria is allowing for strain optimization without the genetically modified label. As effective delivery and establishment of bacteria onto the plants is difficult, current research is exploring the use of endophytes as their residence in the plant helps overcome delivery and survival difficulties. There is still room for improvements to formulation and of stress tolerance of the bacteria to extend shelf-life and improve field survival.

QuickRoots (http://www.tjtechnologiesinc.com/) markets a combination of a bacterium *B. amyloliquefaciens* and a fungus *Trichoderma virens* as a seed inoculant for enhancing plant health via increased root vigor and size and ability to take up nutrients. No claims for the product are made for BC activity. As both organisms have multiple plant growth-promoting mechanisms, including plant hormone production, enhancement of nutrient uptake, etc., BC traits are often not claimed. It is much simpler and cheaper to register a product as a fertilizer than as a pesticide.

Fungi

It is estimated by the FAO that 14% of global crop production is lost to plant diseases, with fungi accounting for 42% and bacteria accounting for 27% (Khan and Anwer, 2011). Ironically, fungi are also important for biocontrol of plant diseases, being responsible for 5% of the value of the biocontrol market (Glare *et al.*, 2012). Like bacteria, fungi are able to control plant diseases via several mechanisms, including antibiosis, competition, exclusion, parasitism/predation, and stimulation of plant defences. Unlike bacteria, fungi actively colonize their environment via hyphal growth, allowing them to better occupy the niches into which they are introduced. The first fungus registered as a biocontrol agent of plant disease with the US EPA was *T. harzianum* ATCC 20476 in 1989. Since then, 18 others have been registered including *Ampelomyces quisqualis* (mycoparasite of powdery mildew), two strains of *Aspergillus flavus* (competitive exclusion of toxin-producing strains of *A. flavus*), *Candida oleophila* (reduces rot caused by *Penicillium* spp.), *Coniothyrium minitans* (mycoparasite of *Schlerotinia*), two species of *Gliocladium*, *Muscodor albus* (a biofumigant of soil), *Pseudozyma flocculosa* (antagonist of powdery mildew), *P. oligandrum* (competition with *P. ultimum*), *Ulocladium oudemansii* (competition with *B. cinerea* on necrotic grape tissues), *V. alboatrum* (induces defense responses in trees, elevating resistance to Dutch elm disease), and six strains of *Trichoderma* (Fravel, 2005). Globally, well over 100 different fungus-based biocontrol products for plant diseases currently exist, sometimes sold as mixtures of different species or strains, and including additional fungi such as *C. verrucaria*, *Phlebia gigantean*, *Metschnikowia fructicola*, *A. niger*, *C. globosum*, *Fomes fomentarius*, *Ophiostoma piliferum*, *V. lecanii*, and nonpathogenic *F. oxysporum* (Whipps and Lumsden, 2001; Kabaluk *et al.*, 2010; Khan and Anwer, 2011). Although species of mycorrhizal fungi may form protective sheaths around plant roots and otherwise aid in plant nutrition and growth, they are not directly involved in controlling plant disease and are sold as biofertilizers, not as biocontrol products.

Trichoderma spp. are common rhizosphere and soil inhabitants found all over the world, and are often the most

prevalent culturable fungi when soil is studied *in vitro*. There are 89 species of *Trichoderma*, all saprophytic and possessing of a number of mechanisms that make them effective biocontrol agents of plant pathogens such as their high reproductive rate, their ability to colonize plant surfaces and interiors, their ability to survive under very unfavorable conditions, a strong mycoparasitism toward a broad range of pathogenic fungi, secretion of a large range of antibiotics and cell wall-degrading enzymes, and their ability to promote plant growth and defense responses. Of the many described strains, *T. asperellum*, *T. gamsii*, *T. virens*, *T. viride*, and especially *T. harzianum* are the most commercially important with many products developed to control soil and seedborne pathogens, including *Pythium*, *Rhizoctonia*, and *Fusarium* spp., and in some cases also *Botrytis*, *Macrophomina*, and *Phytophthera*. Although there is much commercial interest in manufacturing *Trichoderma* products, the fungus also lends itself conveniently to on-farm growth and application in small fermentors directly connected to irrigation systems. In many countries, particularly in South and Central America, such as Costa Rica, growers manufacture their own products for use in various production systems such as rose cultivation (Figure 1). Binab T is the name of the first fungal biocontrol registration to the US EPA, and is made by BINAB Bioinovation of Sweden for control of wood wound diseases of trees by a strain of *T. harzianum*. Another EPA-registered *T. harzianum* product, Root Shield® made by Bioworks Inc. (Victor, NY, USA) protects roots by quickly colonizing plant surfaces and parasitizing soil-transmitted plant pathogens such as *Pythium*, *Rhizoctionia*, *Fusarium*, *Thielaviopsis*, and *Cylindrocladium*. Over 100 *Trichoderma* products can be found such as Trichodermil SC in Brazil (*T. harzianum*), Trichosav in Cuba (*T. harzianum*), Tenet in New Zealand (*T. atroviride*), and Trichotech in Kenya (*T. asperellum*). *Trichoderma* is used for biocontrol in over 60 countries, with the greatest use in the USA, Brazil, and China (Kabaluk *et al.*, 2010).

Next to *Trichoderma*, *Gliocladium* spp. are the most common fungi used in biocontrol of plant pathogens and share similar ecological niches, also being cosmopolitan soil saprophytes. *Gliocladium virens*, which may actually be *T. virens*, has been formulated into products such as Gliogard™ and Soilgard 12 G™ that protect against root rot caused by *Pythium* and *Rhizoctonia* by parasitizing them, producing antibiotics, and excluding them from the root niche. *Gliocladium catenulatum* parasitizes *Pythium, Rhizoctonia, Botrytis, and Fusarium* spp., attacking these pathogens through aggressive hyphal

Figure 1 Utilization of *Trichoderma* for control of foliar and soilborne diseases of roses in Costa Rica. (a) *Trichoderma* is cultured on boiled rice. (b) Rice is suspended in a bucket of water and the dispersed spores sprayed onto foliage. (c) Remaining rice from bucket is spread on soil surface where sporulation occurs again in 24 h. (d) Disease-free rose production – low cost, safe, effective.

puncturing of cell walls. *Gliocladium catenulatum* is registered and is sold as Primastop® by Kemira Agro Oy of Finland, who recommends its application to soils, roots, and foliage to reduce the incidence of damping-off in the greenhouse. Another formulation, sold as Prestop® in Canada and Europe, protects against damping-off, foliar diseases, gummy stem blight, gray mold, root rot, seed rot, stem rot, storage diseases, and wilt.

Viruses

As a biocontrol measure, viruses are attractive ways to combat plant pathogens as they are nontoxic to eukaryotes, are specific to certain microbial species or strains, and are easy and inexpensive to isolate, produce, and store. Currently at the global level, viruses represent approximately 3% of the value of the biocontrol market, although this is mostly due to the popularity of baculoviruses for insect control (Glare *et al.*, 2012). Most plant diseases are caused by fungi, then bacteria, both of which have a large diversity of attendant viruses which might find use as biocontrol agents in the future.

Fungal viruses (mycoviruses) were first discovered as the causal agent of a serious disease of cultivated mushrooms (*Agaricus bisporus*) in the USA in 1962 (Ghabrial and Suzuki, 2009) and since have been found in every major group of fungi. Interestingly, fungal viruses are not known to have natural vectors and thus are transmitted intracellularly by hyphal fusion between vegetatively compatible individuals and from generation to generation via spores. In searching for a means of biocontrol in maize of the biotrophic fungus *Ustilago maydis*, Allen *et al.* (2011) discovered a strong antifungal protein transferred from a mycovirus to its fungal host. The killer protein, KP4, kills all noninfected strains of *Ustilago*, clearing the way for the virus-infected fungus to colonize the inside of the plant. This is likely the product of coevolution between fungus and a virus, which depends completely on survival of its host for transmission and its own survival. Transgenic expression of the protein was found to result in very high levels of antifungal activity against corn smut throughout the plant.

Although most fungal viruses cause no obvious phenotypic changes to their host, a small proportion do, stimulating changes in growth rate, color, morphology, fertility, and reproductive behavior, sometimes leading to a reduction in virulence to plants (hypovirulence) or an increase in virulence (hypervirulence). For use in biocontrol, it is the capacity of a mycovirus to stimulate hypovirulence in plant pathogenic fungi that has attracted the most attention. An important example of mycovirus-induced hypovirulence is with *Cryphonectria parasitica* by the Hypoviridae viruses. *Cryphonectria parasitica* was introduced into North America and Europe from Asia in the early twentieth century and it has killed billions of mature American and European chestnut trees. Hypovirulent strains of *C. parasitica* discovered in Italy in 1950 were employed by the French Ministry of Agriculture in large biocontrol programs starting in the 1960s with the belief that they would competitively exclude virulent strains of *C. parasitica* from infection sites in the chestnut tree. Such biocontrol programs are still used in Europe to control the spread and severity of chestnut blight. The high diversity of vegetative compatibility groups in North American populations of *C. parasitica* has limited the usefulness of this approach.

Bacterial viruses, called bacteriophage, are fundamentally different from mycoviruses in that they can infect bacteria from an environmental source (such as soil or a foliar spray), and thus show more promise for the development of bacterial biocontrol agents. The first plant bacterial pathogen-infecting viruses were discovered in 1924 by Mallman and Hemstreet who showed that the filtered liquid collected from decomposed cabbage was able to inhibit the growth of *X. campestris* pv. *campestris* on cabbage. The cause of bacterial growth inhibition was found to be lytic bacteriophage. Similar experiments with carrots, potatoes, cotton, and corn infected with species of *Erwinia*, *Xanthomonas*, and *Pantoea* suggested that these bacteriophages could play a role in biocontrol of bacterial plant pathogens in agriculture. Bacteriophages are strain-specific, requiring blends of phages to properly target pathogenic microbes. For control of fire blight on apple blossoms caused by *Erwinia amylovora*, three types of phages were combined and significant (37%) disease reduction was obtained. The use of phages for biocontrol of bacterial wilt of tobacco, citrus canker, citrus bacterial spot, bacterial blight on geranium, bacterial blotch of mushroom, and *Xanthomonas* blight of onion are being tested (Jones *et al.*, 2007).

The efficacy of bacteriophage treatments can be improved through coapplication with adjuvants such as traditional antibacterial treatments of copper and streptomycin, and live forms of bacterial and fungal treatments such as Blossom Bless (*Pantoea agglomerans* P10c; Gro-Chem NZ Ltd), and Superzyme (*B. subtilis*, *Trichoderma*, and *Pseudomonasputida*; JH Biotech Inc.). Though typical bacteriophage research focuses on direct killing of the pathogenic bacteria, research with the φRSM3 virus of *Ralstonia solanacearum* (a temperate filamentous virus which does not kill its host but changes it physiology and promotes continuous leakage of viral particles) has shown that inoculation of plants with infected bacteria can prime the plant's own induced defences and protect against bacterial wilt (Frampton *et al.*, 2012). Another line of research is taking endolysin genes from bacteriophage of *C. michiganensis* and overexpressing them transgenically in tomato xylem to kill the invading bacteria that cause bacterial wilt and canker (Frampton *et al.*, 2012). The first commercially available bacteriophage therapy for plant disease protection only recently became available, made by Omnilytics of Salt Lake City, Utah. The product is called Agriphage, and controls *X. campestris*, cause of bacterial spot in tomato and peppers, and *P. syringae* pv. *tomato*, the causative agent of bacterial speck on tomatoes (Frampton *et al.*, 2012). Agriphage is registered with the EPA (Registration no. 67986-1) for control of bacterial spot in Florida as part of an officially recommended integrated management program. A weakened form of zucchini mosaic virus was also registered for use in viral cross-protection (similar to vaccination) of small cucurbit plants against virulent forms of the virus.

Postharvest Control

It is estimated that 20–25% of harvested fruits and vegetables succumb to decay (Sharma *et al.*, 2009). Many aspects of crop storage lend themselves well to biocontrol measures: the crop is usually stored in a defined environment (temperature and

humidity), the agent is applied directly to the target, and the target has high value. In contrast to biocontrol of foliar and soilborne diseases, postharvest disease control involves applying the biocontrol agents directly to the harvested product. In many cases, the biocontrol agent is applied immediately before harvest to prevent any wounds generated during harvest from being colonized by pathogens. This protects a crop that has a latent infection from manifesting during postharvest storage. Organically grown fruit, a growing market, represents an ideal target sector as synthetic chemical fungicides are prohibited.

Most pathogens causing postharvest losses are necrotrophs, that is, they kill host cells and consume the dead tissues. For this reason, competitive exclusion by aggressive nutrient-consuming biocontrol agents is a commonly reported mechanism of protection against these diseases. For a postharvest biocontrol agent to work well, it is critical that it grows well in the storage conditions. Other proposed mechanisms of postharvest biocontrol include antibiotic production and direct parasitism of the pathogen. Whereas first-generation postharvest biocontrol measures were not widely used due to poor control compared to chemical means and lack of economic incentives, second-generation biocontrol agents have made improvements. These new products contain live cells with salts to stabilize the organisms, and lytic enzymes (chitosan or lysozyme) as adjuvants to improve control. In addition, new products are targeted to be combined with chemical and physical methods to increase the efficacy while still using lower quantities of chemicals than conventional control methods.

Commercially, several biocontrol products are available to control postharvest diseases. One of the most successful examples is the use of atoxigenic strains of *A. flavus* to control aflatoxin-producing strains of the same species. Atoxigenic strains compete for the same niche and interact with toxin-producing strains to decrease their population and the amount of aflatoxin produced in cotton seed meal. Aflatoxin has been implicated as a carcinogen in several animal models, and grain with this toxin at low levels cannot be used to feed livestock, nor can any product contaminated with aflatoxin be used for human consumption. Use of competitive, atoxigenic *Aspergillus* strains on peanuts has reduced aflatoxin production by up to 98%. A commercial product, Aflaguard (Syngenta) has been developed for use on a wide variety of crops to effectively reduce aflatoxin contamination.

Another example of postharvest control is interference of pathogen signaling mechanisms. This mechanism has been demonstrated to work on soft rot of vegetables caused by *Pectobacterium carotovora*. This organism requires a critical cell density to express virulence genes, including pectinases which degrade vegetables in storage. The cells sense their density by producing signaling molecules called *N*-acyl-homoserine lactones (AHLs). Naturally occurring bacteria have been identified which degrade AHLs. When vegetables are coinoculated with both the AHL-degrading strain and *P. carotovora*, the rotting is less than with *P. carotovora* alone. Although no commercial products are currently available, this mode of action provides great promise.

Using a novel culturing method, researchers isolated several antagonists of postharvest rotting. The traditional method to identify antagonists was to screen for antibiotic production on agar media in Petri plates. Instead, fruit was washed and this washing fluid was used to inoculate wounds infected with the rot pathogen (Wisniewski *et al.*, 2007). Organisms were isolated from those wounds that failed to rot. This yielded strains of *Candida* that parasitized hyphae of pathogens and produced lytic enzymes.

Several products are available commercially for postharvest BC. Fungal products include Aspire (Ecogen), which is *Candida oleophila*, and YieldPlus (Lallemand), which is *Cryptococcus albidus*. Bacterial products include Serenade (Agro Quess), a *B. subtilis*, and BioSave (Jet Harvest Solutions) which is *P. syringae*.

Biocontrol agents are used sparsely in postharvest control disease measures. This represents an area underexplored and an untapped market as consumers demand less or no pesticides on the produce they consume.

Future Directions

The concepts of BC will continue to expand as molecular technologies accelerate the understanding of the mechanisms by which biological pest control is achieved. It is likely that instead of using biocontrol organisms directly their genes or gene products are increasingly used for management of pathogens. This has already been achieved with Bt. By having the plant produce the toxin, only those insects that feed on the host plant are impacted while the impact on nontarget insects is minimized. This minimizes factors associated with variable efficacy such as formulation, storage, application, and environmental factors. Moreover, the biocontrol product is produced only where it is needed. Sources for such genes will expand and will provide plant breeders with virtually unlimited capacity to create disease resistance in crop plants.

Instead of biocontrol products using single organisms with only one mode of action, one can expect to see more consortia of many types of bacteria, fungi, and viruses that interact with each other and their host. For this to happen one should be able to identify microorganisms that can exist in an ecosystem together and that can promote increased expression of genes having a role in biocontrol. Such communities may already be present in or on plants (as found with sugarcane) and in soils. It is very likely that the agricultural practices, such as plowing, has impoverished soil microbial populations. It is also possible that by breeding for stress tolerance and yield only, many beneficial plant–microbe associations are eliminated. Model systems are now examining how bacteria producing varied compounds including auxin, acetoin, and phenazines influence the efficacy of BC (Kim *et al.*, 2011). Future research will lead to integration of complex and diverse traits into plant genomes and to more effective strategies of microbially mediated biocontrol of plant diseases.

The delivery and establishment of microorganisms that reside on the external parts of plants will continuingly be improved. More focus will be about microbial establishment on seeds and seedlings as they represent a convenient and efficient way to disseminate the microbes, while allowing for rapid and early colonization of the developing plant. The most important criteria for a biocontrol agent is that the application be compatible with growers' practices in the field.

It is very likely that many new species of BC agents will be discovered. Only 1% of soil bacteria have thus far been isolated in culture. Sequencing experiments routinely show that most of microbes in an environmental sample are unknown. For example, the study of the rhizosphere from potato roots by 454 sequencing of the chaperonin Cpn60 gene marker showed that when the 10 most common bacteria expected are isolated, greater than 40% of the isolates turned out to be new species. Similar phylogenetic studies of the microbiology of roots and soil are now coming out at a furious speed and will eventually be accompanied by isolation and characterization of these unidentified organisms and their role on/in the life and health of the plant. Just as plant breeders had no way to identify the presence of microbial associations (other than rhizobia) in their crosses, it is likely that the crop plants of today have lost important associations required for productivity in systems where environmental stresses are the norm. These associations, however, may still be present in their wild parents. It would not be a surprise to find that the next iteration of agriculture looks to insert beneficial plant–microbe associations as new traits into the development of more environmentally sustainable agricultural practices.

Glossary

Anhydrobiosis State of reversible dormancy induced by desiccation.
Chemigation Application of a pesticide through irrigation systems.
Detritus Nonliving organic particles.
Geographic information system (GIS) Geographic information system refers to information system that integrates, analyzes, and displays geographical data.
Global positioning system (GPS) A satellite-based navigation system that provides free location and time information anywhere on earth and in any weather conditions.
Metazoan Taxonomic group comprising the multicellular animals.
Phylum Taxonomic category between kingdom and class.
Vector An organism that transmits disease-causing to another host.

Introduction

Nematodes are commonly known as roundworms. They are the most abundant metazoans on earth with an estimated 80% of all animals belonging to the phylum nematoda. The number of species has been estimated between 500 000 and 10 million. They inhabit nearly every location on earth that contains at least some water periodically. They have digestive, nervous, excretory, and reproductive systems but respiratory and circulatory systems are absent. Internal turgor and longitudinally oriented muscles allow for snake-like movement (lateral undulation) in water films. The body is covered with a cuticle that is primarily composed of the fibrous protein collagen. Most of these unsegmented worm-shaped organisms live unnoticed by the general public because of their typically microscopic size, transparent, colorless body, hidden habitat and a diet of microorganisms or detritus. Although the vast majority of nematode species are considered beneficial because of their function in the food web and their nutrient cycling ability, the ones that parasitize humans, animals, and plants can cause considerable physical and economical hardship. Consequently for nearly one and a half centuries people have tried many techniques and products, including the use of natural and synthetic chemicals to protect themselves and their livelihood against these pests. While medications against mammalian-parasitic nematodes are termed anthelminthics, plant protection products against plant-parasitic nematodes are referred to as nematicides. Botanical or microbial extracts are often further distinguished as bionematicides. The term nematicide refers to chemical compounds that kill, inhibit, or repel nematodes or manipulate their behavior to mitigated crop damage. In general, the use of nematicides might be considered when other methods of crop protection against plant-parasitic nematodes are not feasible or are economically prohibitive. Alternatives to nematicides may include physical, biological, and cultural practices. Another important guideline is the economic damage threshold. This is expressed as the nematode population density that is predicted to cause economic loss exceeding the cost for the treatment. It is more a practical rule than a precise one, as it is influenced by various parameters such as virulence of the nematodes, host physiology, soil type, and temperature. In some cases, the nematode management choices are very limited. For example, certain countries may require nematicide treatments as a sanitary condition for allowing imports of specific produce.

Nematode-caused damages occur in almost any crop worldwide. Diagnosis of nematode-related damage is often difficult because of the lack of specific symptoms. In dense field plantings, oval-shaped areas of pale yellow, stunted, and wilted plants indicate potential root disease problems which might be related to plant-parasitic nematodes or other soilborne pathogens. With increasing spread of the nematode this often becomes less obvious as the whole field suffers under chronic disease pressure, lacking the comparison to healthy plants (Figure 1). Below-ground roots may be short, stunted, discolored, or in unusual abundance, all unspecific symptoms that may be related to other biotic or abiotic causes. An exception is the root galling induced by root-knot nematodes (*Meloidogyne* spp.), which is sufficiently distinct from similar symptoms to be diagnostic. In fruit, nuts, and vine orchards significant nematode parasitic activity might occur for years

Figure 1 Preseason soil treatment (left) with a nonfumigant nematicide revealed chronic lesion nematode (*Pratylenchus* spp.)-caused disease in wheat in the nontreated part of the field (right).

 doi:10.1016/B978-0-444-52512-3.00180-7

before unthrifty growth and yield and/or quality decline alert the grower to a problem. Mixed populations of two or more parasitic species and interactions with soilborne microorganisms increase the difficulty of proper diagnosis. Consequently, correct identification of nematode species and population density is the first step in determining potential pest management strategies, including the use of nematicides.

Plant parasitic nematodes feed exclusively on living tissues, either on the outside (ectoparasitic) or inside of plants (endoparasitic). Their protrusible, hollow mouth stylet enables them to puncture plant cells and inject metabolites that may alter host physiology and morphology as well as ease the feeding process. A muscular thorax pump (metacarpus) provides the force for feeding on the cell contents. Depending on the nematode and plant species, the host–parasite relationship might be very complex with a series of recognition and response events. The details of these processes are still largely unknown but of importance for future nematicide development as they might reveal potential key targets for novel approaches.

The life cycle of plant parasitic nematodes includes distinct stages with four molts: egg, four juvenile, and adult. With endoparasitic nematodes the second-stage juvenile (J2) is often the infective stage. Both sexes are present in most species but mating is not always necessary for fertile offspring. Sex attraction guided by specific female metabolites (pheromones) has been shown with various species. The economically most important root-knot nematodes can produce hundreds of eggs that are contained in a gel-sack, deposited mainly on the outside of the host roots. The gel gives the eggs some protection against desiccation and microbial attack. Other nematodes often survive years in a dormant stage. For example with cyst nematodes, the egg-containing body of the dead adult female (cyst) provides some protection against biotic and abiotic factors. In other species, nematodes in a state of anhydrobiosis have not only a better chance to survive severe drought conditions but also are less susceptible to nematicides.

Nearly all plant parasitic nematodes dwell at least part of their life in soil while the economically most important species eventually become sedentary in roots. A few species occur in above ground parts such as bulbs, leaves, or seeds. The rate of nematode development is species-specific and primarily temperature dependent. For example, in warm climates, endoparasitic root-knot nematodes may go through their life cycle in less than 4 weeks and generate more than one generation on a single susceptible crop. In contrast, in temperate climates eggs of cyst nematodes remain dormant through the winter resulting in the completion of only one generation. This affects not only crop damage but is also important in considering nematicide application scheduling, efficacy, and cost/benefit ratio of nematicides. With multiple nematode generations, even efficient control at the beginning of a cropping season typically does not reduce nematode population density at harvest. In fact, the early protection often leads to a larger, healthy root system, and an increase in potential nematode feeding sites. This may result in more females and increased egg production. However, seedlings are typically more susceptible and damage-prone than older plants. The early nematicide protection might, therefore, sufficiently mitigate nematode damage to justify the cost of the treatment even though there is no difference in population densities at the end of the season. For some plant parasitic nematodes, temperature sum models have been developed to determine the approximate timing of the appearance of the next generation. These predictions can be useful to optimize crop management practices such as split or multiple nematicide applications to coincide with hatching when infective juveniles are most susceptible. Endoparasitic stages are better shielded against nematicides than soil-dwelling stages. In addition to the physical protection, nematicides in plant tissues are likely to be diluted and metabolized. After orchard removal, remaining larger roots often stay alive in soil for months or even years. They continue to provide endoparasitic nematodes and other plant pathogens with nutrition and protection. This reservoir is extremely difficult to eliminate even by some soil fumigants, and contact nematicides are ineffective.

Plant parasitic nematodes are capable of causing plant diseases and significant crop damage. A few nematode species in the family Longidoridae and Trichodoridae function as vectors of important plant viruses. Other nematode species predispose host plants to fungal or bacterial diseases. Nematicides have played an important role to demonstrate such interaction and to mitigate the resulting disease. In addition, many plant health problems are frequently the result of complex and poorly understood interrelationships with plant parasitic nematodes, soilborne fungal and bacterial plant pathogens or deleterious microorganisms, and abiotic stress. The etiology may be further modulated by mycorrhizal and rhizobial symbionts and other rhizosphere or endophytic microorganisms. Thus, nematicide use needs to be viewed not only in regard to the target organisms but also the ecosystem as a whole. For further information of the biology, ecology, and damage potential of plant parasitic nematodes, the interested reader is referred to several reference books (Barker *et al.*,1998; Chen *et al.*, 2004; Perry and Moens, 2006).

Historic Synopsis

The history of nematicides is fairly short but rich in lore from serendipitous discoveries to systematic high-throughput industrial screening; from scientific triumphs to technological disasters. The discovery of *Heterodera schachtii* in 1859 by botanist Hermann Schacht was one of the earliest reports of a plant parasitic nematode and the first of major agricultural and economic significance. Nearly half a century earlier, after Napoleon Bonaparte banned British ships from entering ports on the European continent, the British Empire imposed a sea blockade on his ships from the West Indies. The lack of cane sugar on the European continent accelerated the adoption of the new sugar beet crop that had been developed by German scientists at the end of the eighteenth century. The beets grew well in fertile soils in central Europe and traditional wide rotation schemes were abandoned in favor of more profitable narrow rotations or monoculture. But by the middle of the nineteenth century the consequences of such poor agronomic stewardship became obvious, particularly in declining sugar beet production fields in the Prussian Province of Saxony

where sugar beet cyst nematodes had built up to economically damaging populations.

Subsequent research by Kühn during the 1870s focused primarily on various management strategies against *H. schachtii* that included the search for chemical solutions to this problem. Phenol and carbon disulfide were among the first compounds tested because they had been previously used against soil-dwelling Phylloxera (*Daktulosphaira vitifoliae*), a tiny aphid-like insect that feeds on certain grape roots. Although the efficacy of these compounds against *H. schachtii* was generally poor at economically feasible rates, it stimulated further search for volatile compounds against all soil pests. It took about another half century before the first major breakthrough in chemical control of plant parasitic nematodes occurred. Obsolete inventory of the tear gas chloropicrin from World War I was experimentally tested against soilborne fungi and nematodes with great success in England and California.

Another major agronomic crisis brought on by monoculture promoted the commercial use of chloropicrin as a soil fumigant. This time the pineapple production fields on Hawaii suffered from a build-up of soilborne pathogens including root-knot nematodes. In the late 1920s, scientists of the Pineapple Research Institute found that there was a good dose–response relation between chloropicrin application rates and a reduction in nematode damage as well as a remarkable increase in pineapple weight in response to the treatments. The use of chloropicrin for preplant soil treatment became standard practice in production as the Hawaiian pineapple companies secured the cheap US military surplus. However, when the supplies dwindled the search for alternatives intensified as the production costs for newly synthesized chloropicrin became prohibitively expensive. In the early 1940s, methyl bromide was discovered as a fumigant with broad-spectrum biocidal activity against fungal pathogens, nematodes, weeds, and insects. With the development of a mechanical fumigant-injection and trapping equipment by Storkan in the 1960s, it became practical to fumigate large acreages accurately, safely, and economically feasible for high-value cash crops.

A key development for establishing Nematology as an important crop protection discipline was the accidental discovery by entomologist Carter of the nematicidal activity of D–D, a mixture of 1,3-dichloropropene and 1,2-dichloropropane while searching for an insecticide against pineapple mealybugs (*Dysmicoccus* sp.). Following decades of further product development and regulatory restrictions, it became 1,3-D or Telone II. Moreover, the discovery gave rise to other effective halogenated hydrocarbons, in particular ethylene dibromide (EDB) in 1944 and approximately a decade later 1,2-dibromo-3-chloropropane (DBCP). In contrast to methy bromide, 1,3-D, EDB, and DBCP had little effect on microbial plant pathogens and thereby left no doubt about nematodes causing plant diseases. They convincingly demonstrate the pathogenic potential of nematodes on crop health and production. DBCP with its low vapor pressure, small application rate and low acute toxicity was safe for perennial crops and allowed use in established orchards and vines. In 1956, metam sodium (sodium *N*-methyl dithiocarbamate dihydrate) came to the market, the first of the so-called methyl isothiocyanate-releasing compounds. It not only controlled plant parasitic nematodes but also had good activity against a wide spectrum of soilborne microorganisms and weeds.

In the 1960s and 1970s, several nonfumigant nematicides were developed that originated as insecticides and allowed postplanting use. Furthermore, some of those compounds were taken up by the plants systemically and potentially affected plant parasitic nematodes within the plant tissues. The nonfumigant nematicides all belonged to the chemical classes of carbamates or organophosphates and acted despite their high acute toxicity at labeled field rates primarily as nemastatic neurotoxins. They prevent the enzymatic breakdown of the neurotransmitter acetylcholine in the synapse, resulting in uncontrolled stimulation of the nervous system. As a consequence, the nematicides stunted nematode movement, feeding, and delayed development for several weeks. But nematodes typically recovered once the concentration of the compounds dwindled to ineffective levels via dilution or degradation. Remarkably, in contrast to insects, resistance of field populations of plant parasitic nematodes to these nematicides has never been demonstrated. However, frequent use favored accelerated biodegradation that shortened the useful residual longevity of the products. However, some persistent compounds were found as pollutants in ground water. Awareness of environmental pollution risk increased correspondingly with improvements in detection methods. One of the most acutely toxic pesticides registered by the US Environmental Protection Agency (EPA), aldicarb, was detected in groundwater in more than half the US states. Various regulatory actions restricted application techniques and nematicide-use rates to increasingly fewer crops and areas. Consequently many products were removed from the US market as their profitability was challenged.

EDB and DBCP were banned in the US in the late 1970s. Lack of proper worker protection in DBCP production facilities resulted in cases of male sterility and suspected carcinogenesis. But it was the detection of the compounds in groundwater that led finally to their cancellation by the US federal EPA. This development was fueled in part by a change in the attitude of the general public toward technology and environment protection.

In the beginning of the 1990s, methyl bromide was included in the Montreal Protocol, an international treaty to reduce the production and consumption of stratospheric ozone depleting substances. Ratified worldwide by nearly 200 countries, it scheduled the gradual phase-out of those compounds. This had tremendous repercussions for high-value annual crops, replanting of fruit and nut trees as well as for nurseries. It is safe to say, the consequences for agriculture will not be fully understood until years from now.

Another legislative act in the US had even more impact on the availability and use of nematicides. Alarmed by a National Academy of Science report on pesticides in the diets of infants and children, the US Congress unanimously decided with the 1996 Food Quality Protection Act to overhaul of the US's pesticide and food safety laws. It included stricter safety standards, in particular for infants and young children, and a periodic reevaluation of existing pesticide tolerances. Both carbamates and organophosphates, and therefore nearly all nonfumigant nematicides, belong among the EPA's first priority group. This was a group of closely related pesticides with

a common mechanism that required cumulative risk assessment. Risk mitigation measures resulted in use restrictions that limited the profit margin of many products, some of which were consequently withdrawn from the market. While most western companies stopped screening for carbamate and organophosphate nematicides in the early 1990s, two of the latest organophosphate nematicides fosthiazate (1992) and imicyafos (2010) were developed in Japan.

As the need for safe solutions to the nematode problems grew, it attracted development of the so-called bionematicides. DiTera, a sterilized fungal fermentation product received US EPA registration in 1996. Since then many botanical-derived products have been developed, targeting primarily specialty markets such tree and vine crops as well as turf. In 2006, the nematicidal seed treatment Avicta was registered in the US on cotton and subsequently on several other crops. The active ingredient abamectin, a mixture of complex microbial metabolites, has long been known for its potent nematicidal activity and has been used as an anthelmintic in animal health.

More recently, the nematicide R&D activities among the remaining agrochemical businesses has considerably increased. At least half a dozen new development products are in near-market testing that supposedly show better environmental compatibility and less acute toxicity with similar target efficacy as the previous generation of contact nematicides.

Delivery of Nematicides

During the past two decades, new plant protection products have been generally more environmentally benign than in previous times, particularly in terms of target specificity and nontarget toxicity. Furthermore, despite substantial reduction in application rates, many newer insecticides and fungicides have similar if not better efficacy than products of previous decades. In contrast, application rates of nematicides have stayed relatively similar with typically 1–9 kg ha^{-1} active ingredients per season for contact nematicides and approximately 120–750 kg ha^{-1} for fumigants. Use changes occurred primarily in response to regulatory restrictions, not so much because of new product or technology development. The reason for this is in part due to a consequence of the consolidation of the agrochemical industry.

One of the main technical problems of using nematicides lies in efficiently delivering the active ingredient to the target site. The majority of plant parasitic nematodes spend at least part of their lives in soil, the rhizosphere, roots, or other subterranean plant parts. Although the growth or mobility range of other plant pathogens is typically very limited, plant parasitic nematodes may occur anywhere from the surface to more than one meter deep in the soil. Therefore part of the target population is quite likely outside the effective treatment zone. They might reinvade the previously nematicide-treated zone by their own mobility after the concentration drops below an effective level. Nematodes are often guided to their host by a gradient of attraction signals. Under favorable conditions, nematicides with a high volatility that move through soil pores achieve a better distribution than low-volatile compounds. The latter require mechanical soil incorporation or movement with water to reach their target. Such resource-intensive applications are often compromised, negatively impacting treatment efficacy. Dissemination inside the treated soil depends on a variety of factors such as compound chemistry, soil type, temperature, water, organic matter content, and pore space. Treatment efficacy is typically better in soils with larger pore space than in heavier clay soils where small pore spaces limit movement of volatile compounds and extensive particle surface provides abundant adsorption sites. Organic matter also diminishes the treatment efficacy by adsorption. Similar limitations must be considered for the use of contact nematicides. In particular the organophosphates are known to lose their efficacy in soils with high organic content. The activity of the carbamate oxamyl, however, diminishes quickly in moist, warm and alkaline soils.

Nonvolatile nematicides are often available in different formulations such as as liquids and granuales. They are typically incorporated into the top 12–15 cm of soil and remain inhibitory to nematodes for a few weeks. To reduce nematicide use and reduce cost, band-application aims to treat primarily the root zone to provide temporary protection against plant parasitic nematodes. Application through low volume irrigation systems (drip systems) takes advantage of water-restricted root systems that are then flushed with a nematicide solution. Although usually by the end of the growing season root damage (galling) and nematode population density are often as large as under nontreated crops, the early protection against invading nematodes and secondary microorganisms may provide sufficiently beneficial effects.

Several carbamate and organophosphate nematicides are acropetally systemic, i.e., they can move from the root to the top of plants, and may affect endoparasitic nematodes after infection although the primary action occurs in soil. Foliarly applied nematicides must be taken up through the epidermis and transported downwards (basipetal, phloem transport). Adjuvants may aid in the uptake of foliar sprays, thereby increasing the efficacy. Currently, only a couple of nematicides have the ability of significant basipetal movement and their efficacy is variable. The paucity of such compounds might be related to the more time-consuming screening and testing for such additional properties compared to a simple dose–response assay.

After the development of contact nematicides, there was a brief interest in their potential use as seed treatments. Although useful activity in protecting the germinating seed and developing seedling was demonstrated, the better and longer lasting efficacy by high rate soil-applications stifled further development. Moreover, the loading rates to achieve significant seedling protection were a delicate balancing act between phytotoxicity and efficacy. As long as high rates of relatively inexpensive soil nematicides were permitted, seed treatments could not compete with their typically short-term protection capability. There was also the concern of bird and other wildlife feeding on seeds treated with highly acute toxic compounds. Perhaps most important, there was little incentive for the agrochemical industry to replace high volume soil applications with low volume seed treatments.

With the advent of high price hybrid or genetically modified seed and the market removal of many old soil pesticides, as well as merger of seed and agrochemical companies, a new marketing model emerged. It set out to provide the grower with 'complete' solutions against a variety of pest and disease

problems by offering quality seed coated with a combination of several pesticides (fungicides, insecticides, nematicides, etc.) for seedling protection. Such portfolio packaging has been controversial as it may reduce competition and limit grower's choices. However, it likely increases safety with respect to pesticide use and handling. It also reduces other operational inputs such as machinery use, fuel, and labor for pesticide applications replaced by seed treatments. Since the recent registration of combination products with the nematicidal components, seed-delivered nematicides have become a new development target. As such products are expected to protect developing seedlings for only a few weeks, this technology would benefit from a combination with additional protection modules.

Nematicidal Compounds

The most commonly known nematicides are listed in Table 1. This listing is neither complete nor does it indicate the current regulatory status for use. There are many more compounds, which at one time or another have been used for the purpose of mitigating the influence of plant parasitic nematodes. The following brief overview will discuss some of those compounds and products that are currently registered or under development in some parts of North America, Southern Europe, or East Asia.

Among the fumigants, 1,3-dichloropropene (1,3-D, Telone II) is considered the only one with primarily nematicidal activity at labeled rates. It is applied either as a volatile liquid that, injected into the soil, converts to gas, or as an emulsified compound for chemigation. It has excellent efficacy as a preplant nematicide. For decades, it was the primary tool for nematode control in many crop production systems. The detection of elevated levels of 1,3-D in the ambient air in a California county led to its suspension. It was reinstated again a few years later with reduced application rates and various other restrictions to address air quality concerns. Further label changes were implemented to reduce volatilization and safety. In combination with chloropicrin, it is considered to be the

Table 1 Products for plant protection use against plant parasitic nematodes[a]

Common name	*Active ingredient(s)*	*Chemical class/organisms*
Terr-O-Gas, Tri-Con, and Brom-O-Gas	Methyl bromide	Halogenated hydrocarbon
Cloropicrin 100 Fumigant and Metapicrin	Chloropicrin	Halogenated hydrocarbon
Telone II and Telone EC	1,3-Dichloropropene (1,3-D)	Halogenated hydrocarbon
Telone C-17, C-35, and InLine	1,3-D plus chloropicrin	Halogenated hydrocarbon
Midas	Methyl iodide	Halogenated hydrocarbon
Enzone	Sodium tetrathiocarbonate	Thiocarbonate
Paladin	Dimethyl disulfide	Organosulfur
Temik and Meymik	Aldicarb	Carbamate
Vydate	Oxamyl	Carbamate
Metam, Vapam, and Sectagon 42	Metam sodium[b]	Dithiocarbamate
K-Pam HL and Sectagon K54	Potassium sodium[b]	Dithiocarbamate
Basamid	Dazomet[b]	Dithiocarbamate
Counter	Terbufos	Organophosphate
Nemacur	Fenamiphos	Organophosphate
Nemathorin and Eclahra	Fosthiazate	Organophosphate
Nemakick	Imicyafos	Organophosphate
Mocap	Ethoprop	Organophosphate
Rugby and Apache	Cadusaphos	Organophosphate
Admire Pro	Imidacloprid	Neonicotinoid
Movento	Spirotetramat	Tetramic acid
Nimitz	Fluensulfone	Fluoroalkenyl (-thioether)
Avicta and Tervigo	Abamectin	Macrocyclic lactones, metabolites of *Streptomyces avermectinius* (syn. *S. avermitilis*)
DiTera	Killed, dried fermentation product	Solids and solubles of *Myrothecium verrucaria* strain AARC-0255
Ecozin Plus 1.2% ME	Azadirachtin derived from Neem	Botanical, extract from *Azadirachta indica*
MultiGuard Protect and Crop Guard	Furfural derived from sugarcane bagasse	Heterocyclic aldehyde, produced from various agricultural byproducts
Nema-Q	Extract derived from soap bark tree	Botanical, extract from *Quillaja saponaria*
Sesamin EC and NeMaX	Sesame oil derived from sesame seeds	Botanical, extract from *Sesamum indicum*
BioNem, BioSafe; VOTiVO, and Nortica	Live microorganisms	*Bacillus firmus* strain I-1582
Clariva	Live microorganisms	*Pasteuria nishizawae*
Klamic	Live microorganisms	*Pochonia chlamydosporia*
MeloCon and BioAct	Live microorganisms	*Paecilomyces lilacinus* strain 251

[a]This list is for general information only. Active ingrediants are often sold under various brand names and many more products claim nematicidal activity. Inclusion on this list does not constitute an endorsement by the author, nor is disapproval implied of products that are not mentioned.
[b]Methyl isothiocyanate releaser (MITC).

preferred alternative to replace methyl bromide for soilborne disease control.

Nonvolatile nematicides belonging to either the chemical class of the carbamates or the organophosphates are acetyl cholinesterase inhibitors that interfere with nerve transmission processes; a process used by many other animals, including humans. These compounds have a higher acute mammalian toxicity than halogenated fumigants but are relatively safe for plants, which allows postplant applications. Their application rates are considerably lower than soil fumigants. Although they do not compare in efficacy to soil fumigants, they usually remain active for several weeks before diluted or degraded. Repeated applications in 2- to 3-week intervals often improve efficacy but increase the risk of enhanced microbial degradation that has been documented for nearly all of these compounds. In cold soils, longer residual time increases the risk of ending up in ground water and wells. Efficacy is very much reduced in heavy-textured and organic-rich soils. Overall carbamate nematicides have dominated the nonvolatile nematicide market.

Aldicarb (Temik) is one of the oldest nonvolatile nematicides with excellent activity against plant parasitic nematodes, insects, and mites. This carbamate is extremely acutely toxic and systemically mobile in plants. These characteristics led to one of the most notorious foodborne pesticide poisoning cases in North America. Nearly 2000 people in California and Oregon fell ill after consuming watermelons illegally treated with Temik. It has been misused like no other pesticide for killing undesirable wild life. The nickname 'Two Step' cynically indicates the acute toxicity and fast lethal action.

There is a rich literature on plant-derived compounds that show some nematicidal or nematistatic activity *in vitro* or in pot tests. Seed extracts of the Neem tree (*Azadirachta indica*) have been insecticidal and nematicidal, primarily attributed to the complex secondary metabolite azadirachtin. Nema-Q is based on extracts of the Chilenean soap bark tree (*Quillaja saponaria*) that contains saponins, tannins, and other potentially active ingredients. The active ingredient in MultiGuard is furfurol, a heterocyclic aldehyde derived from sugar cane extracts. Other plant-derived products contain various essential oils, compounds with detergent-like characteristics or glucosinolates. Chitwood (2002) addressed such compounds in a comprehensive review. However, the active ingredients of botanical extracts are often not known. In most cases, the activity at realistic field application rates is at best marginal and highly variable. Composition of plant metabolites and their activity may vary with source, age, storage conditions, and extraction process, which make quality control of each production batch a critical issue. Some products are promoted by unsubstantiated producer claims and user testimonials that lack scientific evaluation. The increasing number of such products is helped by the lack of efficacy requirement for federal EPA registration.

Among the group of biological-derived compounds, the avermectins stand out as important pharmaceutical and agricultural products. Avermectins were discovered in a collaborative project between the Kitasato Institute in Japan and the Merck, Sharpe and Dohme (MSD) research laboratories in the US. After isolation of various Actinobacteria from soil near a Japanese golf course, one of them tested highly anthelmintic in mice that served at MSD as a model for human helminth infections. It was a chance discovery as later attempts to reisolate the organism *Streptomyces avermectinius* failed. This was the first commercial nematicide that was discovered in a nematode screen before its insecticidal and acaricidal properties were shown. Exposure to abamectin results in fast and permanent inactivation of the nematode's movement and feeding ability. This is due to binding to glutamate- and gamma-aminobutyric acid-gated chloride channels in nematode nerve cells that keeps the channels open. The unregulated influx of chloride ions causes irreversible paralysis. After years of use as an anthelmintic and in foliar sprays against insects and mites, recently abamectin has been developed in various crops as a seed coating to protect seedlings against plant parasitic nematodes.

Combination of Nematicides with Other Techniques

The use of nematicides with other plant protection agents is most often seen in combinations of 1,3-D with other soil fumigants that have little or insufficient activity against plant parasitic nematodes. The combination with chloropicrin expands the spectrum of activity and frequently results in synergistic activity that increases the efficacy against various pathogens. Recently, pesticide combinations in seed coatings showed considerable benefits for seedling growth and health. This was related to the effects plant parasitic nematodes exert on young seedlings. Apart from the feeding damage, nematodes can significantly change the plant's morphology and physiology. For example, in cotton *M. incognita*-infested roots became more susceptible to seedling disease and wilt. The soilborne fungus *Rhizoctonia solani* was attracted to the weakend host tissues and caused severe seedling damping-off. Protection against the nematodes and the fungus by a seed coat combination of several fungicides and the nematicide abamectin reduced the incidence of damping-off more than with a seed coating of only fungicides. Similarly, the cotton cultivar Pima S-7 is resistant to *Fusarium oxysporum* f. sp. *vasinfectum* race 1, but parasitism by *M. incognita* race 3 renders the cultivar susceptible to the wilt. Seed coating with abamectin and a fungicide/insecticide combination provided good protection against the nematodes during the critical seedling stage. In the presence of both the root-knot nematodes and the fungus, seedlings grown from abamectin plus fungicides/insecticide-coated seeds of Pima S-7 did not show any disease symptoms such as stunting, chorosis, and vascular discoloration that were typical for seedlings grown from seeds coated with only the fungicides/insecticide.

The combination of nematicides with biological control agents has not received much practical attention. One of the difficulties most soil-applied pesticides share is that protection demands an extended residence time in soil, which might then lead to potential environmental pollution. Consequently, the effective protection period is limited to a few weeks. In contrast, biological control organisms of endoparasitic nematodes are typically not very effective against the mobile juvenile stages that cause the initial seedling damage. Parasites of sedentary stages, however, can substantially reduce nematode population growth by castration or destruction of the adult

females. As nonvolatile nematicides have been found compatible with most fungi and bacterial biological control organisms, a combination of both strategies should limit their weakness and extend the protection period.

Although genetic host resistance is generally considered the most important nematode management tool, it might not be effective to prevent damage to a young seedling or a tree if planted in a field highly infested with plant parasitic nematodes. Nematicide treatments are recommended to achieve protection during the time the young plants are most susceptible. In tree and vine crops, such treatments can prevent damage that may affect the tree health for decades. For example, the grapevine fanleaf virus is transmitted by the dagger nematode *Xiphinema index*. Without effective soil fumigation, it will take more than a decade to safely replant an old vineyard site with a previous infestation. Proper use of nematicides may also lower the risk of developing resistance-breaking races of plant parasitic nematodes or to extend the useful life of a resistant cultivar. Nematicides can be an important part of crop rotation when there are no suitable nonhost or resistant cultivars to at least temporarily protect a susceptible host against nematode damage. This is often the case in warmer climates where the wide host range of root-knot nematodes make it difficult to devise an economically feasible rotation.

New Approaches

Regulatory restrictions on nematicides are often viewed negatively by growers and commodities as they initially limit the available tools and strategies to combat a serious foe. But in the long run, similar challenges to other pesticides have been met with the development of superior compounds and innovative technologies. The search for alternatives to soil fumigants and nematicides has already resulted in some remarkable developments, such as emulsified 1,3-D formulations for chemigation, combination of products with increased efficacy (1,3-D/choropicrin combinations) and improved tarpaulin covers that reduce treatment rate or increase efficacy while mitgating emissions (Yates *et al.*, 2011). Other innovations in preliminary stages of development will be briefly noted in the following paragraphs.

Seed treatments with contact nematicides developed in the 1970s have never been widely adopted. Low loading rates to avoid phytotoxicity and short persistence of the seed-delivered nematicide did not compete well in efficacy with the permitted high rates of soil-applied nematicides. Seed companies concentrated on genetic traits, not on pesticide coatings. To compete with other seed providers, the least expensive fungicide treatment was sufficient. This changed when agrochemical industries acquired biotechnology and seed companies. Superior hybrids and genetically modified crops were developed that increased the value and price of their seed. Consolidation of the various agrobusinesses resulted in development of product bundles that include hybrid seed with various seed-delivered plant protection products. After years of optimizing the treatments for microbial pathogen and insect protection, this product branding has now expanded the focus to protection against plant parasitic nematodes. Small amounts of nematicides, tens of grams active ingredient (a.i.) per hectare

Figure 2 Cucumber seed coated with the nematicide abamectin (0.3 mg a.i./seed) (right) mitigated early season attack of root knot nematodes (*Meloidogyne incognita*) compared to the nontreated control (left).

in the case of abamectin, protect crop seedlings against nematode attack during the most critical time of plant development (Figure 2). This compares favorably to several kilograms a.i. per hectare with soil-applied nematicides. Perhaps most exciting, there are now opportunities for additional modules to support and extend the protection period, for example with foliar nematicide sprays that are taken up by the plant and transported downward to the roots, and/or with biological control agents that interfere with nematode reproduction.

Nematicides are typically uniformly applied throughout a field, although distribution and population density of plant parasitic nematodes are far from uniform. A population density map would allow concentration of nematicide applications only to those areas where nematodes are expected to be present in significant number or to adjust the rate according to the predicted population density. Obtaining this information from nematode enumeration of extracted soil samples is cost-prohibitive for even a very low resolution map. However, soil texture can be a relatively good predictor of potential nematode population densities as most plant parasitic nematodes prefer coarse-textured, sandy soils. Electrical conductivity of soil is strongly correlated to soil particle size and texture; it increases from sand to silt to clay. Global positioning system/Geographic information system guided soil electrical conductivity systems can quickly and inexpensively produce field maps that predict potential nematode population levels. Limited soil sampling is performed to confirm population density predictions. Nematicide application guided by georeferenced soil electrical conductivity maps provides a promising techology for site-specific, variable-rate treatment of plant parasitic nematode-infested fields. A consortium of researchers in the southeast US that developed this technology found reduction in nematicide use by 30–50% in large-scale tests whereas yields remained unchanged or increased (Mueller *et al.*, 2010).

Planting site-specific application of soil nematicides is another development that attempts to reduce application rates, cost, and nontarget effects while retaining effective protection

against plant parasitic nematodes. This idea goes back to a time when tree and vine planting sites were treated with fumigant injections from a hand-held device. But advances in global positioning technology make this formerly hazardous and time-consuming method safe, effective, and economically feasible. Key elements are real-time kinematic satellite navigation and virtual reference stations that provide real-time corrections, allowing the application of soil fumigants/nematicides with pinpoint precision and at an economically feasible cost.

Nematicidal compounds might affect a range of processes in nematodes that are highly specific and therefore less likely to interfere with nontargets. The discovery and development of novel nematicides typically involves a number of approaches to find molecules with significant activity against nematodes. Sources may include inhouse produced or externally purchased synthetic compounds, microbial or botanical metabolites, and patent- or literature-guided synthesis. Agrochemical companies formerly screened several thousand synthetic and natural compounds per year against particular target sets of plant pathogens and pests, including plant parasitic nematodes. With advances in molecular biology and bioinformatics, chemogenomic screening systems now analyze huge molecule libraries with use-specific efficacy information to identify new metabolic targets and biologically active compounds. For optimization of lead molecules in efficacy, specificity or persistence, computational approaches are utilized to find molecular similarities related to nematicidal activity. Bioinformatic-supported chemists rely on large molecule databases and utilize quantitative structure-activity relationship models. Structural chemical scaffolds, the essential parts of a molecule thought to posess nematicidal activity, are then manipulated by computer-aided modeling and design tools. High-throughput screening assays evaluate the new generation of compounds with the previous leads. It is expected that such development effort will result in novel compounds with high nematode-specific activity but low acute mammalian toxicity and overall better environmental compatibility than currently used nematicides.

Outlook

For the past 70 years, nematicides have been important plant protection tools that improved agricultural production by ensuring yield quantity and quality under high disease pressure from plant parasitic nematodes. This was especially true where traditional diversified farming gave way to large-scale production relying on narrow rotations or monoculture. In most developed countries, plant parasitic nematodes may be responsible for an average of 5% reduction in attainable crop yield, whereas it is at least 15–20% in many other countries. In subtropical and tropical areas, crop damage caused by root diseases is more common and severe as most plant parasitic nematodes and their associated secondary pathogens thrive in warmer climates. Nematode-caused problems are likely to increase in the future due to global climate change and economic production constraints. But the success of chemical nematode control has been questioned, as real and perceived problems have emerged related to environmental pollution, hazardous manufacturing risks, nontarget exposure to highly toxic chemistry, and poor product stewardship. Ironically, the attempts by growers, commodities, and third-party distributors to hold on to old nematicidal products is counterproductive to the replacement with safer and even more effective compounds. The relatively small market compared to other classes of pesticides and the generally high cost for developing pesticides has left nematicide R&D to a dwindling number of agrochemical companies. Although the scientific discovery process has continued to advance, new products need to justify the development cost that is currently estimated at approximately US$200 million. With an estimated US$1 billion in sales, nematicides make up only 2.5% of the worldwide pesticide market. This appears to be small in contrast to the annual damage by plant parasitic nematode that is estimated at approximately US$130 billion worldwide and US$11 billion for the US. An even more realistic estimate would consider crop damage caused by interactions between plant parasitic nematodes and other soilborne pathogens or by including reduced grower's returns due to adjusting to less susceptible but also less profitable rotation crops. With the development of economically effective and ecologically acceptable nematicides, their global market could easily double or triple. In the future, plant protection against plant parasitic nematodes will increasingly rely on a combination of integrated nematode management tactics that require long-term planning to implement multiple nematode population reduction strategies, including the use of nematicides.

Glossary

Antibiotic Any of a large group of chemical substances, as penicillin and streptomycin, that are produced by various microorganisms and fungi, have the capacity in dilute solutions to inhibit the growth of or to destroy bacteria and other microorganisms, and are used in the treatment of infectious diseases.

Fungicides Resistance Action Committee (FRAC) An industry technical committee dedicated to the management of fungicide resistance.

Fungicide resistance The naturally occurring, inheritable adjustment in the ability of individuals in a population to survive a plant-protection product treatment that would normally give effective control.

Fungicides Fungicides are biocidal chemical compounds or biological organisms used to kill or inhibit fungi or fungal spores.

Plant pathology (phytopathology) The scientific study of plant diseases caused by pathogens (infectious organisms).

Introduction

It is a well-known and often-published fact that the world population is growing, especially in the less developed countries of the world. Statistics from the United Nations (UNFPA) predict the world population will grow from the current seven billion to more than nine billion by 2050, with clear consequences on the quantity of food that will need to be produced to avoid widespread hunger. Sixty years ago, farmers had to feed two people from every hectare. Their grandchildren now have to feed more than twice as many. In addition, the pressure on land continues to grow. Some new land will come into agricultural production in the coming years, but other areas will be lost to urbanization and erosion. Worldwide, there are now more people living in cities than in the countryside. Outdated farming practices, deforestation, and other man-made factors also continue to cause erosion.

In addition to the effects of this increase in the number of people, it is clear that diets are changing and will continue to do so. In Asia in particular, increasing wealth has led to a preference for more variety in the diet, and more meat and poultry are now being eaten. As a consequence of the lower energy efficiency of a meat-based diet compared with the direct consumption of grain (rice, wheat, maize, etc.), this dietary change will continue to drive further increases in the global demand for grain crops. Finally, the quite recent demand for biofuels, although today quite small with regard to the use of cereals, is predicted to grow and will also add to the global requirement for grain. Of course, the increasing demand for food has an impact much beyond grain crops, and demand will increase for all major crops including legumes, vegetables, and fruits.

All of the above is happening at a time when the world stocks of crop commodities are at their lowest levels for many years and, as a consequence, the world price level of many commodities such as rice and wheat have risen dramatically with very significant consequences in the affordability of food to many millions of people. Put together, it is clear that the world is leading toward an ever-greater scarcity of food, which has even been referred to as a world food crisis.

The available statistics all add up to a clear situation, with clear consequences for the future – the world needs to grow more food from the available land and with the available water in a sustainable manner. The area of agriculturally productive land is likely to stay stable at approximately 1.5 billion hectares; the population is likely to increase by approximately 80 million per year. Among the many threats to crop production on a worldwide basis is the damage to these crops caused by pests (including fungal pathogens, insects, and weeds). Crop losses due to such pests have been calculated to be substantial and crop-protection techniques and products have been developed to reduce these losses and make crop productivity as high as possible.

Economic Impact of Plant Diseases and the Need to Control Them

Plant diseases are known from times preceding the earliest writings. Fossil evidence indicates that plants were affected by disease 250 million years ago. The Bible and other early writings mention diseases, such as rusts, mildews, blights, and blast, that caused famine and drastic changes in the economy of nations since the dawn of recorded history. Other plant disease outbreaks with similar far-reaching effects in more recent times include late blight of potato in Ireland (1845–60); powdery and downy mildews of grape in France (1851 and 1878); coffee rust in Ceylon (starting in the 1870s); Fusarium wilts of cotton and flax; southern bacterial wilt of tobacco (early 1900s); Sigatoka leaf spot and Panama disease of banana in Central America (1900–65); black stem rust of wheat (1916, 1935, 1953–54); and southern corn leaf blight (1970) in the United States.

Estimates of actual losses in crop production worldwide have been published by Cramer (1967) and Oercke *et al.* (1994) and recently updated for major food and cash crops for the period 2001–03 (Oercke, 2006). Although weeds are overall the most important pest group in crop production worldwide, the incidence and impact of pathogens is also substantial (Table 1). The actual losses shown in this table comprise the crop losses sustained despite the crop

 doi:10.1016/B978-0-444-52512-3.00179-0

Table 1 Estimated loss potential from pathogens and actual losses in six major crops worldwide in 2001–03

Crop	*Attainable production (Mt)*	*Crop losses (%)*[a] *due to*			
		Pathogens		*Total crop pests*	
		Potential	*Actual*	*Potential*	*Actual*
Wheat	785	15.6 (12–20)	10.2 (5–14)	49.8 (44–54)	28.2 (14–40)
Rice	933	13.5 (10–15)	10.8 (7–16)	77.0 (64–80)	37.4 (22–51)
Maize	891	9.4 (8–13)	8.5 (4–14)	68.5 (58–75)	31.2 (18–58)
Potatoes	518	21.2 (20–23)	14.5 (7–24)	74.9 (73–80)	40.3 (24–59)
Soybeans	245	11.0 (7–16)	8.9 (3–16)	60.0 (49–69)	26.3 (11–49)
Cotton	79[b]	8.5 (7–10)	7.2 (5–13)	82.0 (76–85)	28.8 (12–48)

protection practices employed. Absolute losses vary among crops depending on their ability to compensate for the effects of pathogen attack, and tend to be higher under conditions of high productivity and where climatic conditions are favorable to the pathogen.

Oercke *et al.* (1994) estimated losses due to plant diseases in the four major crops (rice, wheat, potato, and maize) to be 10–16% of potential production which translated into approximately US$64 billion in the years 1988–90. The losses increased to US$84 billion when the top eight crops were included. This is not including the recent uprising of Asian rust of soybean, where losses are reported to be up to 80%, and the projected losses in the main growing regions of Brazil are 2.2 million tons (US$487.3 million at 2004 crop prices) (Yorinori *et al.*, 2005). Since these figures were published, the prices of agricultural commodities have increased significantly (in some crops such as soybeans and wheat they have doubled) and, therefore, the financial impact of crop losses due to diseases in 2011 was considerably greater. In addition to yield losses caused by diseases, also to be considered are postharvest quality losses and the possible accumulation of toxins during and after the cropping season. Although food security is a critical issue in the developing world, food safety has become a dominant concern in the developed world; however, the critical importance of food safety is now recognized, at last, in the developing world as well (e.g., Wild and Gong, 2010).

In the case of potato late blight caused by *Phytophthora infestans*, crop losses can be complete. Indeed, potato late blight was famously the cause of the Irish potato famine, a period of mass starvation, disease, and emigration between 1845 and 1852. During the famine, approximately one million people died and a million more emigrated from Ireland. Use of crop protection measures, which include chemical fungicides, obviously has not completely prevented crop losses, but they have significantly contributed to productivity and quality of produce worldwide. In many regions, crop protection measures have enabled farmers to increase crop productivity considerably without losing an uneconomically unacceptable proportion of the crop to pests. Crop yields would be approximately half their current levels if no crop protection measures were implemented. However, even with crop protection, approximately a third of crop yields are still lost to weeds, diseases, and insects. These data show that there are still significant advances in crop protection practices, including chemical disease control, which need to be made in order to maximize worldwide crop production and avoid unnecessary losses. Crop yields will probably have to increase by approximately 50% on a global level by 2030 to ensure food security. This implies a higher annual rate of yield gain than has been achieved in the major grain crops in recent years and has led to calls for a 'second green revolution.'

A benefits study carried out for USA agriculture in 2005 quantified the economic impact of the use of fungicides to US crop production (Gianessi and Reigner, 2005). This study covered 50 crops and concluded that, for the 231 diseases considered, fungicides are the primary means of defense from fungi. As a result of fungicide application, yields of most fruit and vegetable crops in the USA are increased by 50–95%. Growers gain US$12.8 billion (44 000 metric tons of crop yield at 2005 crop commodity prices) in increased production value from the control of plant diseases caused by fungi. The yield gains attributable to the use of fungicides range from 20% to 100%, with the greatest gains tending to be achieved in fruit and vegetable crops. Furthermore, the authors conclude that the benefit of fungicide use in US agriculture is a significant increase in the production of fruit and vegetables, which are so important for the healthy diets of Americans. They even went as far as stating that because fungicides are so important in United States food production, it is worth asking whether there should be policies adopted to assure that American growers have the fungicides that they need for the foreseeable future.

In Europe, the economic impact of plant diseases has recently become a more important consideration for several reasons. These include the general food security and safety issues already described, plus assessments of the impact of the withdrawal from sale of various fungicides alongside other plant-protection products due to new legislation in Europe. The potential impact of a reduction in availability of fungicides on the market in Europe would include the possibility that growers are unable to control some diseases in crops due to the unavailability of effective solutions. In addition, there could be a longer term effect on the sustainability of the remaining fungicides due to an increased likelihood of resistance issues. Such an impact assessment has been carried out for the wheat crop in Europe (NOMISMA, 2012). The

conclusions of this study are that, with no fungicides available at all, yield losses in European countries range from 7% in Denmark to 25% in France. For durum wheat grown in Italy, this yield loss is estimated at 28%. If no triazole fungicides were available due to the European legislation, the immediate impact on conventional wheat yields is calculated to be 5–9% with a longer term impact of 10–15% yield loss due to resistance arising to other classes of fungicides due to a reduction of numbers of modes of action. It can clearly be understood from these examples that the global economic impact of plant diseases is very high and, therefore, the use of interventional measures such as fungicides to prevent losses in quantity and quality is essential. Comprehensive, up-to-date yield and economic loss data due to plant pathogens are surprisingly few and difficult to find; in these times of increased concerns over food security and safety, there is a need to evaluate these losses more carefully in order to help the setting of priorities in research and development (R&D), and in actions at field level (Savary *et al.*, 2012).

The Control of Plant Pathogens

To protect crops from diseases, there are several crop production and protection options. Conventional and organic farming use good agronomic practices to reduce the incidence of damaging diseases, for example, the choice of crop cultivars resistant or tolerant to diseases, crop rotations to minimize the carryover of pathogens, soil cultivations to bury infested crop residues, among others. Organic crop production relies largely on these practices alone and, although sustainable, yields in organic crop production are in general significantly lower than under conventional management. However, these yield differences vary between crops and, to a certain extent, also between countries and regions analyzed. Cereal yields in organic production are typically 60–70% of those under conventional management although vegetable yields are often just as high as under conventional management (Offermann and Nieberg, 2000). Few data are available on pasture and grassland yields in organic farming; reported values lie in the range of 70–100% of conventional yields, depending on the intensity of use. Taking organic cereal yields at 60% of conventional systems, this equates to a requirement of 67% more area to produce the same yield. When faced with a growing world population, the need to feed them, and growing urbanization, this land is unlikely to be available. On the contrary, an increase in intensity of crop production is most likely to be required.

Resistance or tolerance to crop diseases through natural traits or genetically modified crops (GMO) is an area under intensive scientific study. Plant breeding for disease tolerance, using classical or marker-assisted selection approaches, is a very important tool in disease management programs and the use of varieties of plants resistant to particular diseases has proved to be very effective, for example, stem rust of wheat, rust of dry bean, and *Rhizoctonia* root rot of sugar beet. It must be realized, however, that the product development time for successful new varieties is similar to that of a new chemical and, in cereals, advances take 12 years to bring benefits to the market (AEBC, 2005). The introduction of genetically modified (GM) crops has, however, been difficult in several other areas of the world (especially Europe) because of consumer and environmental concerns. Examples of tolerance to important crop pathogens achieved by GM have been few, however, and, to the author's current knowledge, except for control of papaya ring spot virus of papaya in Hawaii and watermelon mosaic virus of cucurbits in the eastern USA, none have been commercially introduced. Whether disease tolerance is brought about by naturally occurring traits or genetic modification, there is always the doubt about the durability of the disease resistance – plant pathogens have an established history of being able to overcome the host resistance of plants. It is probable that even if disease tolerance becomes successfully implemented in major economic crops such as cereals, potatoes, or soybeans, these traits will themselves require protection through the integrated approach of using chemical fungicides in programs to manage the diseases and avoid the tolerance breaking down.

Biological control methods have been proven to be very effective in certain situations, most notably in the control of several insect pests with natural predators, or with 'biopesticides' such as *Bacillus thuringiensis*. Biological control approaches do exist against plant pathogens, based on organisms such as *Coniotherium minitans*, *Bacillus subtilis*, and others, and under the right conditions can be very successful. Biological control of plant diseases in major agricultural crops has, so far, only met with limited success; such disease control agents are covered in another article in this encyclopedia.

The control of crop diseases with chemical fungicides has had a successful history for more than a century. They are integral to the production of crops in many countries of the world, resulting in increased yields and farmer income. Economic benefit studies show conclusively that, without fungicides for control of plant pathogens, production of some crops would be impossible in parts of the world (Gianessi and Reigner, 2005; Cook and Jenkins, 1988; Cuthbertson and Murchie, 2003). Fungicides have been responsible for ensuring the production of many crops over many years, such as protection of the potato crop against late blight as already mentioned or security of banana production in Central America. Cooke (1992) wrote that 'without the use of fungicides, large scale commercial potato production in Ireland would be impossible.'

Modern fungicides can be applied to crops using a range of technologies depending on the characteristics of the chemical and also according to the most effective way to target the disease in question. The majority of fungicide use today is applied using conventional spraying techniques to the foliage of plants. This technology has the advantage of being practical and convenient (growers have on-farm spray equipment that can be used for a wide range of crop protection products including herbicides and insecticides), as well as being a very good way to target predominantly foliar diseases with a range of fungicides that may have contact or systemic activity. There may, however, be some limitation of this technology, for example, in the requirement for quite high water volumes to ensure distribution of some fungicides, or the potential for spray drift; and it may not be the most appropriate time in the life cycle of the pathogen to target.

Application of a fungicide to soil has proved to be very effective for some soilborne pathogens. Examples of such use include soil applications of phenylamide fungicides such as mefenoxam to control *Pythium* spp. and soilborne *Phytophthora* spp. as well as the control of *Rhizoctonia* spp. by strobilurin and other fungicides. Further targeted application can be achieved through treatment of seeds with fungicides, a technology also used for insecticides. Seed treatment is clearly the most targeted application for fungicides against seedborne diseases such as bunts, smuts, leaf stripe of barley, seedling damping-off diseases, *Fusarium* spp., and many others. It is also a highly valuable technology for the control of pathogens that infect the crop systemically, either from a seedborne inoculum or from soilborne infections. Examples of such diseases include downy mildews of corn and peas (*Peronosclerospora* spp. and *Perenospora viciae*), against which conventional foliar sprays are much less effective than a targeted seed treatment. Seed treatment can also be effective against other soilborne pathogens, such as *Pythium* spp., *Rhizoctonia* spp., and *Fusarium* spp. Soil or seed treatment application are particularly effective delivery technologies for fungicides that are systemic in nature and thus have the ability to move into the plant and protect actively growing areas of stems, leaves, and roots. Owing to the long duration of disease control that can be conferred by such treatment methods, they are considered to be risky in terms of resistance management of foliar diseases. For this reason, soil and seed treatment applications of fungicides against foliar diseases have been discouraged by the Fungicide Resistance Action Committee (FRAC, www.frac.info).

Plant pathogenic bacteria cause many serious diseases of plants throughout the world (Vidhyasekaran, 2002), but fewer than fungi or viruses, and they cause relatively less damage and economic cost (Kennedy and Alcorn, 1980). The most important diseases caused by bacteria in plants include fire blight (*Erwinia amylovora*), bacterial blights in a range of vegetable crops caused by *Pseudomonas* spp. and *Xanthomonas* spp., bacterial leaf blight in rice caused by *Xanthomonas oryzicola*, and a range of bacterial soft rots and cankers. Many of these diseases can be devastating when environmental conditions are favorable, for example, fire blight, which can destroy whole production orchards of apple and pear trees. Many plants, both economic and wild, have innate immunity or resistance to many pathogens and the first line of control of plant pathogenic bacteria is through host-plant resistance. In addition, seed certification schemes are essential in some crops such as potatoes to control, for example, blackleg. Good agricultural practice, cultivations, and crop rotation are essential tools to minimize the effects of bacteria in commercial crops. However, these measures do not result in complete success and it is a fact that bacterial diseases in crops are difficult to control. Chemical control measures are few and tend to have only a moderate level of success – key products include copper and antibiotics. Some success has been achieved with the use of biological control agents. Some success has also been achieved with the resistance-inducing compounds such as acibenzolar-*S*-methyl, which are able to activate the plant's natural defense mechanisms including those against fungal and bacterial plant pathogens.

Challenges for Developing Chemical Agents for Plant Disease Control

According to industry studies (McDougall, 2010), a new crop protection product takes approximately 10 years and approximately US$250 million to be developed (from discovery to first sales). On average approximately 25%, and as much as 40%, of this cost is invested in researching toxicological risks, environmental fate, and impacts. The achievement of identifying a new active ingredient is only the start of the R&D process. For every active ingredient tested in early laboratory screening, only one in tens or hundreds of thousands actually makes it to the market. This is because there are a number of different obstacles that need to be overcome before a crop protection product is ready to go to market. According to market analysis, on average, the 15 leading crop protection companies spend approximately 7.5% of sales on R&D, amounting to a R&D expenditure in 2011 of more than US$6 billion (agrochemical and crops/traits combined – agrochemical investment was US$2.6 billion in 2011) (McDougall, 2012). This ratio places the plant science industry among the most R&D-intensive business sectors.

Fungicides, as is the case for all crop protection chemicals, must be targeted to meet the needs of farmers and growers, to solve the problems that regularly limit the productivity (yields) and quality of produce. They must answer these 'biological crop needs' and, at the same time, must be cost-effective to make their use worthwhile. At the same time, the target markets need to be viable to the company inventing and producing the products to justify the large investment of money and resources required to fully develop the products, bring them to the market, and support them in the market place. In addition to these requirements, products must meet modern-day requirements for human and environmental safety, and be compatible with other crop protection practices, avoiding undesired effects on, for example, beneficial organisms. Fungicide markets change and so do the market potential of crop/disease combinations. For example, while the worldwide market for the control of powdery mildews has traditionally been targeted by most agrochemical companies for new products, it has become apparent that, on its own, this market has become critical in terms of a cost–benefit ratio for industry. In other words, the high level of investment required to bring a new, powdery mildew-specific fungicide to the market is becoming difficult to justify against the rather crowded and limited market. Indeed, there are very few 'single disease,' targets that are financially viable for the development of a new chemical fungicide. Exceptions to this may be Septoria leaf blotch (*Mycosphaerella graminicola*) in Europe, and Asian Soybean Rust (ASR) (*Phakopsora pachyrhizii*) in Latin America. Increasingly, however, a broad-spectrum fungicide that is used to control a wide range of plant diseases across crops and regions is required to pass the economic hurdles of R&D.

Changes in the biology of plant diseases also have an impact on disease control and therefore on the targeting strategies of fungicide discovery in the R&D companies. Resistance of plant pathogens to fungicides is an important factor leading to the constant search for fungicides with new modes of action that are, on the one hand, not cross-resistant with other

fungicides on the market that may have problems with resistance, and ideally themselves having a novel mode of action that is of low risk of resistance arising. These two requirements are particularly challenging – it is difficult to invent a completely new mode of action by design with no scientific lead at all (which is why fungicide researchers look to other, existing fungicides in crop protection as well as human medicine for inspiration). At the same time, the prediction of the risk of resistance arising to the new mode of action is a great challenge requiring intensive studies and knowledge in each case. Ideally, the fungicide would have multiple modes of action to confer a low resistance risk, but these so-called multisite fungicides can have their own difficulties in passing registration hurdles due to the generally nonspecific modes of action involved. However, it is possible to discover such fungicides, as shown by the success of chlorothalonil and mancozeb. New needs and opportunities can also open up for the control of plant diseases such as the spread of ASR in soybeans in Latin America (a fungicide market estimated at more than US$1 billion), which is today an important target for new fungicides. Forecasting these biology and market changes is particularly difficult and challenging, considering the long timelines required to bring a new fungicide product to market and, therefore, is another factor in the complexity of new product invention and development.

Therefore, it will be realized that the search for the 'ideal' fungicide is complex and difficult. This is because there is a wide combination of properties of the fungicide that need to be considered and met. These include:

Biologically efficient:
- high selectivity (on target),
- fast impact (action),
- optimal residual effect,
- good plant tolerance, and
- low risk of resistance development.

User friendly:
- low acute toxicity,
- low chronic toxicity,
- good formulation characteristics,
- safe packaging,
- easy application method, and
- long storage stability.

Environmentally sound:
- low toxicity for nontarget organisms,
- fast degradation in the environment,
- low mobility in soil,
- no relevant residues in food and fodder, and
- low application rate.

Economically viable:
- good cost/profit ratio for the farmer,
- broad use,
- applicability in Integrated Crop and Pest Management,
- innovative product characteristics,
- competitive, and
- Patentable.

To meet all these needs and successfully bring a new active substance to the market is a real challenge to industry. To achieve a high level of potency (activity) against a target pathogen while having minimal or no effect on the crop, on beneficial organisms, and on humans and other mammals is extremely difficult. There has been a large effort by academia and industry in recent years to use target-site modeling in order to produce 'designer molecules' to selectively inhibit fungi at specific target sites and in that way find new modes of action for products although avoiding target sites known to be problematic in terms of mammalian toxicology. However, this has proved to be extremely difficult in practice and there have been, to the author's knowledge, no product successfully discovered and developed using these techniques. It also appears that the trend that started a number of years ago of the so-called 'high throughput screening' and combinatorial chemistry, where a huge number of randomly selected chemicals are screened for biological activity against a number of key target diseases, has proved no more successful than other approaches. The concept is that, according to the laws of averages, the greater the number of chemicals that are screened, the greater the chance of finding interesting biological activity that can then be further optimized. This approach, however, has proved to be somewhat too untargeted and has been largely abandoned.

The current approach in industry is still very much around optimization in known chemical classes and modes of action, although at the same time much research goes into the area of discovering new classes of fungicidally active chemistry and, hopefully, new modes of action. All companies have their own key 'search targets,' that is a clearly defined research strategy defining what they want a new product to look like, what its characteristics should be, and, therefore, what the market potential will be. These search targets include elements such as a completely new mode of action against the key diseases, and may be also multiple sites of action (multisite) or at least a very low risk of resistance. These requirements are easy to define and state – but success in discovering such solutions remains a real challenge. As a consequence, it is a fact that many of the novel fungicides brought to the market recently, as well as several due to be introduced to the market over the next few years, are site-specific fungicides, acting against the pathogens at a single binding site in a biochemical pathway. From a product safety point of view, this tends to be a good thing, especially if the target pathway is one that does not exist in mammals. However, from the consideration of resistance risk, and consequently the long-term sustainability of the product in the market, this might not be so favorable, depending on the nature of the mode of action, the pathogen and the consequences to the pathogen of the genetic changes needed to adapt to the fungicide.

History of Fungicides

The first chemical means for controlling plant disease in a practical way was discovered by B. Prévost in 1807. Bunts and smuts of cereals had been a key limitation to cereal cultivation for centuries, appearing unexpectedly on healthy-looking plants that should have been producing grain. Prévost was the first to observe that spores, which grew into tiny germinating 'plants,' caused wheat bunt. He then made the discovery that a weak copper solution (generated when he held the spore

suspension in a copper vessel) prevented their growth. Through experimentation, he showed that farmers could control bunt by wetting wheat kernels with a copper sulfate solution. Copper-based seed treatments remained popular in some countries, including France, through the end of the twentieth century. It was in the latter half of the nineteenth century that chemical disease control really started to develop. Sulfur had long been known to have therapeutic properties. In 1824, a recommendation was made for it to be used to control powdery mildew of peaches (Robertson, 1824), and, in 1848, sulfur dust was recommended for control of vine powdery mildew (*Uncinula necator*) and other powdery mildews. Lime sulfur, prepared by boiling lime and sulfur together, seems to have been first mentioned in 1833 by Kenrick as a means of controlling vine powdery mildew. Copper sulfate was tried as a foliar spray for various diseases but was found to be phytotoxic on some crops. Sometime before 1862, lime was added to the copper sulfate to reduce its damaging properties, initially to reduce damage to wheat seed. Lime sulfur did not control downy mildew of vines (*Plasmopara viticola*), but, in 1882, Millardet noticed that, where a liquid made from lime and copper sulfate had been applied to vines near roadways in order to discourage thieves from stealing the grapes, there was far less downy mildew. One of the best known fungicides, Bordeaux mixture, was thus announced in 1885. Fungicidal preparations based on the active ingredients of sulfur, lime, and copper sulfate dominated chemical disease control into the early twentieth century.

The major products used from 1940 up to the present day are listed in **Table 2**. Early chemical disease control was largely aimed at horticultural crops (fruits and vegetables) as well as seed treatments. Concerns for the products' impact on the environment were largely nonexistent, as were concerns for the applicator. Most users prepared their own fungicides from basic recipes. Proprietary products were available at this time for those who did not want to take the time and trouble to make their own. Before the introduction of the dithiocarbamates, the testing of which was described by McCallan of Cornell University in 1930, most of the products used as fungicides were applied at high rates, for example, 10–20 kg a.i./ha for sulfur against powdery mildew on grapes. The products did not always give good control, could be phytotoxic, and had to be applied frequently. The current use rates of well below 100 g ha^{-a} for many triazole fungicides against the same pathogens that these high-rate older fungicides were used against is a 200-fold reduction. From 1940 to 1970, there were a number of new chemistry classes introduced as fungicides. Among these, the dithiocarbamates, the phthalimides, and the benzimidazoles represented major innovations and improvements over the previously used inorganic fungicides, being significantly more effective at lower use rates and less phytotoxic. The lower use-rates of these fungicides made them easier for the grower to use and gain successful disease control. The decade from 1960 to 1970 saw a rapid expansion of R&D together with a rapid growth of the fungicide markets. In this decade, the most widely used protectant fungicides, mancozeb and chlorothalonil, were introduced. The decade also gave us the first broad-spectrum foliar systemic, thiabendazole, and the systemic seed treatment carboxin.

From 1970 to 1980, the rate of innovation in the fungicide industry continued to increase with approximately 30 new fungicides being introduced. Agriculture was booming in Western Europe and the Americas at this time, government-funded research into crop protection was increasing, the importance of crop diseases and their control was increasingly understood, and, as a consequence, industry stepped up their invention processes to discover totally new chemical classes and modes of action. Key introductions to the market during this time included carbendazim, the first major triazole fungicides (triadimefon and propiconazole), key novel

Table 2 Key fungicide introductions from 1940 to the present day

Year	*Fungicides*	*Number*
1940–60	Thiram, zineb, nabam, biphenyl, oxine copper, tecnazene, captan, folpet, fentin acetate, fentin hydroxide, anilazine, blasticidin S, maneb, dodine, dicloran	13
1961–70	Mancozeb, captafol, dithianon, propineb, thiabendazole, chlorothalonil, dichlofluanid, dodemorph, kasugamycin, polyoxins, pyrazophos, ditalimfos, carboxin, oxycarboxin, drazoxolon, tolyfluanide, difenphos, benomyl, fuberidazole, guazatine, dimethirimol, ethirimol, triforine, tridemorph	24
1971–80	Iprobenfos, thiophanate, thiophanate-methyl, validamycin, benodanil, triadimefon, imazalil, iprodione, bupirimate, fenarimol, nuarimol, buthiobate, vinclozolin, carbendazim, procymidone, cymoxanil, fosetyl-Al, metalaxyl, furalaxyl, triadimenol, prochloraz, ofurace, propamocarb, bitertanol, diclobutrazol, etaconazole, propiconazole, tolclofos-methy, fenpropimorph	29
1981–2000	Benalaxyl, flutolanil, mepronil, pencycuron, cyprofuram, triflumizole, flutriafol, penconazole, flusilazole, diniconazole, oxadixyl, fenpropidin, hexaconazole, cyproconazole, myclobutanil, tebuconazole, pyrifenox, difenoconazole, tetraconazole, fenbuconazole, dimethomorph, fenpiclonil, fludioxonil, epoxiconazole, bromuconazole, pyrimethanil, metconazole, fluquinconazole, triticonazole, fluazinam, azoxystrobin, kresoxim-methyl, metaminostrobin, cyprodinil, mepanipyrim, famoxadone, mefenoxam, quinoxyfen, fenhexamid, fenamidone, trifloxystrobin, cyazofamid, acibenzolar-*S*-methyl	42
2001–Present	Picoxystrobin, pyraclostrobin, dimoxystrobin, prothioconazole, ethaboxam, zoxamide, fluopicolide, flumorph, fluoxastrobin, benthiavalicarb, iprovalicarb, mandipropamid, boscalid, silthiofam, meptyldinocap, amisulbrom, orysastrobin, metrafenone, ipconazole, isotianil, proquinazid, ametoctradin, sedaxane, penflufen, isopyrazam, penthiopyrad, bixafen, fluopyram, fluxapyroxad	29 plus other pipeline products

fungicides for the control of downy mildews and late blight such as metalaxyl and cymoxanil, and the amine fungicide fenpropimorph.

In the following 20-year period from 1980 to 2000, agricultural markets continued to increase at first, but, in time, overproduction of crops such as cereals resulted in a slowing down of the agrochemical market, especially in Western Europe (where a large proportion of the fungicide sales were made). At the same time, new legislation was introduced concerning the requirements to bring new crop-protection products to the market, notably in the USA (Environmental Protection Agency (EPA)), and Europe (introduction of European Directive 91/414). At this time, experts forecasted a dramatic decrease in the numbers of innovative new products that would be brought to the market as a consequence of the new legislations and the concomitant increase in the costs of bringing new products to the markets. Indeed, for a number of years the rate of introduction of new products slowed dramatically because of delays by regulatory authorities in implementing the new rules and the sheer increases in workloads caused. During this period, there were fewer new active substances registered, but innovation continued with an increasing number of different fungicide mixtures, innovative formulation types, and novel packaging solutions to enable manufacturer to continue to differentiate and bring new ideas to the markets. Over time, in fact the investments made by agrochemical companies continued to increase. As a consequence, more than 40 new fungicides were discovered and introduced successfully to the market during that period. These innovations included the next generation of significant new triazoles, including epoxiconazole, and cyproconazole, difenoconazole, as well as completely novel chemistry with new modes of action such as fludioxonil, pyrimethanil, cyprodinil, acibenzolar-S-methyl (ASM), and the groundbreaking new strobilurin fungicides, namely, azoxystrobin and kresoxim-methyl. The triazole and strobilurin fungicides formed the basis for today's continued successes in these chemistries, which consist of a great proportion of fungicide sales around the world.

From the year 2000 up to the present day, industry has continued to invest and has been successful in the discovery of new fungicides. Since the year 2000, many major new introductions have been made to the market, including 'new generation' triazoles and strobilurins, and further chemistries with new modes of action such as metrafenone, mandipropamid, proquinazid, and boscalid. This continued rate of new product introductions by R&D-oriented agrochemical companies is a demonstration of the continued commitment to agriculture by the chemical industry, which has resulted in increasing investment by companies into the future, despite rising costs and the threats of declining markets and generic competition. This contrasts strongly with the pharmaceutical industry where, despite increasing R&D expenditure, the rate of innovation has fallen dramatically.

Overview of the Main Classes and Uses of Modern Fungicides

As discussed in the Section History of Fungicides, many fungicides have been invented and commercialized over the past 50 years with varying levels of success. It is not possible to fully cover each of these fungicide classes and fungicides in this article, only to give a summary overview of those which are of the greatest commercial importance globally at the present date. Comprehensive publications are available that cover these and many more fungicides in more depth, for example, Lyr (1995) and (Krämer *et al.*, 2012). Market statistics for 2011 (McDougall, 2012) given in **Table 3** show that the most important fungicide classes by sales value today are the triazoles and strobilurins, followed by mancozeb and the succinate dehydrogenase inhibitor (SDHI) fungicides. The multisite fungicides chlorothalonil, copper, and mancozeb, and the highly systemic and active benzimidazole and phenylamide fungicides also have significant sales of US$300–600 million. These numbers show the worldwide success of triazoles and strobilurins, which is due to their broad-spectrum nature of disease control and their high levels of efficacy and yield/quality protection. It is equally clear, however, that the fungicide market is dominated in site-specific modes of action by only three, which has an implication in terms of fungicide resistance (see Section Fungicide Resistance and its Management). In addition, it is apparent that the older multisite fungicides have a particular value, largely as tools for use in resistance management mixtures and programs to protect the newer site-specific fungicides. Of course, these multisite fungicides are also important as standalone fungicides in their own right, but usually have limitations in terms of flexibility of application, timing in the disease epidemic (most effective when used completely protectively at the early stages of pathogen attend and not curatively), and, unlike the more systemic modern fungicides, are not able to protect new crop growth. In the 2011 market, the class of SDHIs is mainly represented by the seed treatment carboxin, and also Boscalid, which has significant sales mainly into fruit and

Table 3 Reported sales of fungicides in the year 2011 by chemical class/mode of action

Chemical class	*Worldwide sales 2011 (US$×1000)*[a]
Demethylation-inhibitors (DMI) (triazoles)	3 273
Quinone outside inhibitors (QoI) (strobilurins and others)	3 261
Mancozeb	620
SDHI	581
Copper fungicides	485
Benzimidazoles	452
Phenylamides	405
Other multisites	311
Chlorothalonil	310
Amines	264
Carboxylic acid amides	250
Anilinopyrimidines	245
Dicarboxamides	175
Other fungicides	2 673
Total	13 305

[a]Calculated values based on data from AMIS., 2012. Crop Protection and Seeds Database. Midlothian, UK: AMIS and Phillips McDougall (2012) (www.Phillipsmcdougall.com).

Abbreviation: SDHI, succinate dehydrogenase inhibitor.

vegetable crops for the control of powdery mildews and *Botrytis* but also to an extent into cereals. With the present-day high level of industry innovation and investment into this class of fungicides, it can be expected that over the next 5–10 years, the SDHIs will be at least as significant as the strobilurins in global sales.

Benzimidazoles

The benzimidazole fungicides were introduced in the late 1960s for plant disease control and were very quickly accepted throughout the world. This was due to their unique properties that included high potency at low use rates, very good crop safety, and their ability to protect new growth of the crop due to their systemic activity. Benomyl was the first of the class to be introduced, soon to be followed by carbendazim, thiophanate-methyl, thiabendazole (mainly used in fruit postharvest treatment) and fuberidazole (primarily used for seed treatment). The benzimidazoles are notable for their broad-spectrum activity against a very wide range of diseases, including most ascomycetes, and some basidiomycetes and deuteromycetes. Key economic pathogens controlled include *Botrytis cinerea*, *Cercospora* spp., *Colletochrichum* spp., *Fusarium* spp., powdery mildews in several crops, including *Erysiphe* spp. and *Oidium* spp., and eyespot in cereals. Benzimidazoles are potent inhibitors of β-tubulin polymerization in many species of fungi. Although direct interactions with β-tubulin seem to be the predominant inhibitory processes for this chemical class, interactions with other forms of tubulin as well as differential interactions with tubulin in the free and polymerized states also have been reported. This single-site mode of action was unfortunately soon discovered to be highly prone to resistance problems and, as described earlier in this article, benzimidazole resistance represented the beginning of serious fungicide resistance problems in the agricultural industry. Because of their very success in terms of excellent disease control, these fungicides were used by growers frequently and, in many cases, exclusively – under these conditions, resistance developed rapidly within two to four seasons. However, where mixtures of benomyl and other unrelated fungicides were used from the beginning, resistance was delayed for several seasons (Delp, 1980). In this way, this class of fungicides became a model for the basis of resistance management principles that are still followed today. Although the market potential of the benzimidazoles has been limited by the resistance problems, they are still used in some markets today. Benzimidazoles are classified by FRAC as high-risk fungicides according to their resistance risk classification scheme.

Sterol Biosynthesis Inhibitors

There are four classes of fungicides that comprise the sterol biosynthesis inhibitors (SBIs). Only three of these classes are used as agricultural fungicides: demethylation-inhibitors (DMI) fungicides, amines (formerly called 'Morpholine' fungicides), and hydroxyanilides. All three classes inhibit targets within fungal sterol biosynthesis but differ in regard to the precise target sites they inhibit. SBI fungicides that inhibit the C_{14} demethylation step within fungal sterol biosynthesis are known as DMIs). Besides the triazoles, numerous imidazoles, pyridines, and pyrimidine all have been shown to act as DMIs. The most important members of the SBI fungicide group are described here.

Triazoles

Triazoles are the largest class of fungicides used in plant-protection, both in terms of number of fungicides developed and launched but also in sales in the current market (Table 3). They are members of the DMI class and are generally characterized by their broad spectrum of activity against a range of economically important pathogens on arable crops, top fruit, vines, plantation crops, etc. Fluotrimazole, first presented in literature in 1973, was the first triazoles fungicide to be marketed. This fungicide was narrow in its spectrum of disease control, being limited to powdery mildew, and was very quickly superseded by the first broad-spectrum triazole fungicides such as triadimefon. Triadimefon was launched soon after fluotrimazole in 1973. This was followed closely by triadimenol (more active than its precursor fungicide, triadimenol) in 1977, bitertenol (1978), and propiconazole (1979). Since the introduction of these highly successful fungicides, numerous other triazoles have been launched for a wide variety of plant diseases across crops as well as for foliar, seed treatment, and postharvest uses, and have been equally successful. Despite the success of the early wave of triazole fungicides, and the high number of this class of fungicides being introduced in the 1980s, innovation in the chemistry continued and more modern more potent triazoles have been commercialized more recently – examples are epoxiconazole (1992) and prothioconazole (2004). One reason for the longevity of this class of fungicides is that, although being highly efficient broad-spectrum products, resistance has only occurred over time as a slow shift resulting in a decreased sensitivity to their mode of action rather than a clear and sharp loss of field performance. Although these sensitivity shifts have resulted in some of the less potent triazoles being ineffective in some disease/crop combinations, the intrinsically more active triazoles push the sensitivity curves back to their original ED_{50} values and remain effective. Sales figures for 2011 show the 'top 10 ranking' for triazoles to be prothioconazole, epoxiconazole, tebuconazole, cyproconazole, propiconazole, difenoconazole, metconazole, myclobutanil, flutriafol, and flusilazole. FRAC classify the DMI fungicides as medium resistance risk.

Other DMI Fungicides

Imidazoles include only a small number of compounds that are active against plant pathogens. Imazalil was the first imidazole fungicide for agricultural uses and is mainly used today as a seed treatment in cereals, but it is also used as a foliar treatment in vegetables and ornamentals and as a postharvest treatment in citrus fruits. Prochloraz is a broad-spectrum fungicide with activity against ascomycetes and *fungi imperfecti*, plus lower activity against basidiomycetes. Prochloraz has been widely used in European cereals, particularly for its activity against eyespot (*Oculimacula* spp.) and also for its activity against key foliar diseases in cereals such as net blotch

and *Septoria* spp. Other members of this class are fenapinil (now discontinued) and trifumizole, used mainly in fruits and vegetables against a wide range of pathogens such as powdery mildew, scab, and *Monilinia* spp. but also as a cereal seed treatment against smuts and bunts.

Piperazines, Pyridines, and Pyrimidines

The only fungicide from the piperazines used in agriculture is triforine, which was used primarily as a foliar treatment against powdery mildew, scab, and other diseases in fruits and other horticultural crops and also extensively as a home and garden product (especially on roses). It has also been used as a seed treatment in barley for powdery mildew control. The pyridines are represented by buthiobate and pyrifenox, both used primarily for powdery mildew control in fruits and vegetables; pyrifenox has a greater spectrum of disease control and is also effective against various leaf spots in fruits, vegetables, and peanuts. Both are today commercially small-market fungicides. Two pyrimidine fungicides were developed and marketed: fenarimol and nuarimol. Fenarimol was developed for use in fruits and vegetables (powdery mildew, scab, rust, and leaf spots), whereas nuarimol was developed mainly for use against cereal diseases as a seed treatment to control seedborne pathogens and airborne powdery mildew, and also as a foliar treatment against powdery mildew and *Rhynchosporium secalis*.

Amines

Similarly to the DMIs, the amines also consist of different chemical classes. The first representatives of this group were chemically morpholines. Although representatives of two other chemical groups (piperidines and spiroketalamines) have entered the market, the group is still (incorrectly) commonly termed the morpholines. Amines inhibit to a variable degree two target sites within the sterol biosynthetic pathway, the Δ^8–Δ^7 isomerase and the C^{14} reductase.

Amines have a narrower spectrum of activity than the DMIs and are best known for their excellent control of powdery mildew and rust in cereals, powdery mildew on vegetables and grapes, and black sigatoka of banana. During the 1980s, fenpropidin and fenpropimorph were key fungicides in the European cereal market, whereas tridemorph was used extensively for the control of black sigatoka. This class of chemistry, although having seen some moderate shifts in sensitivity by some pathogens in the past (e.g., sigatoka in Central and South America, powdery mildew in cereals in Western Europe), remains effective and is still extremely valuable in crop protection today, including those uses where historical shifts occurred. Indeed, owing to resistance problems of cereal powdery mildews toward triazole fungicides during the mid-1980s, the morpholine fenpropimorph and the piperidin fenpropidin gained rapidly in importance as partners for the resistance management of triazole fungicides, because amines are not cross-resistant to DMIs. The latest introduction within the amine group is spiroxamine, which is a representative of a new chemical class within fungicidal amines, the spiroketalamines. Other amine fungicides in agriculture are dodemorph and aldimorph. The current ranking of global sales (2011) is: spiroxamine, fenpropidin, fenpropimorph, and tridemorph. Amines can be used alone but are often used in mixtures with DMIs to control powdery mildews and rusts.

Hydroxyanilides

Currently this class is represented by fenhexamid. Hydroxyanilides inhibit the C3-keto-reductase step in ergosterol biosynthesis. Hydroxyanilides have a narrower spectrum of activity than the DMIs and amines – fenhexamid is a specific botryticide, which does not show cross-resistance to other classes of anti-*Botrytis* fungicides.

Dicarboximides

The activity of dicarboximide fungicides was first reported in the early 1970s (Fujinami *et al.*, 1971) with three key commercial products being introduced within 3 years: iprodione (Lacroix *et al.*, 1974), vinclozolin (Pommer and Mangold, 1975), and procymidone (Hisada *et al.*, 1977). They are typically protectant fungicides and, although some claims to systemic activity have been made (Hisada *et al.*, 1977), they are best regarded as protectant materials.

Compared with many other classes of fungicides, their activity spectrum is relatively narrow but includes species from the following genera: *Botrytis*, *Sclerotinia*, *Sclerotium*, *Monilia*, *Alternaria*, *Phoma*, *Didymella*, *Rhizoctonia*, and *Laetisaria* (*Corticium*). Current fungicides in this class on the market are iprodione, vinclozolin, and procymidone. They are sold alone and as components of many coformulated mixtures. Dicarboximides were originally introduced for control of *B. cinerea*, primarily on vines where they were welcomed due to the occurrence at the time of resistance to the benzimidazole fungicides. As mentioned previously in this article, resistance management strategies were poorly understood at the time and this inevitably led to overuse of the products such that resistance developed very quickly. *Botrytis* remains the main fungus at risk, although resistance in other genera can easily be found. Even after approximately 30 years of research, the mode of action of dicarboximides is still not certain. Recent evidence (for review see Yamaguchi and Fujimura, 2005) suggests that they interfere with the osmotic signal transduction pathway consisting of histidine kinase and MAP kinase cascades.

Quinone Outside Inhibitor Fungicides

The quinone outside inhibitors (QoIs) class of fungicides represent one of the most widely used groups of fungicides used today to control agriculturally important fungal pathogens. In addition to the strobilurins, the group includes famoxadone, fenamidone, and pyribencarb, all chemically distinct from the strobilurins but with the same mode of action and contained within the same cross-resistance group. Indeed, eight chemical classes of QoIs can be identified to date. The strobilurins were first commercialized in 1996 with the launch of azoxystrobin and kresoxim-methyl, and since this date there has been a steady stream of new QoI fungicides launched with several more identified in company pipelines.

There was a rapid uptake in the market of the strobilurins and within only a few years they were registered and sold in over 80 crops in 70 different countries (Bartlett *et al.*, 2002). Sales of strobilurins and other QoI fungicides amounted to approximately US$3.2 billion in 2011, representing 20–25% of the total global sales of fungicides. Sales of azoxystrobin alone in 2011 were approximately US$1.2 billion million making it the world's biggest selling fungicide.

The discovery of the strobilurins was inspired by a group of natural fungicidal derivatives of β-methoxy-acrylic acid, the simplest of which are strobilurin A, oudemansin A, and myxothiazole A. These derivatives are produced by the basidiomycetes *Strobilurus*, *Mycena*, and *Oudemansiella* but were found unsuitable to be produced commercially as fungicides because of their photochemical instability and volatility. However, the knowledge of their structures and physical properties provided the starting point for many researchers to start to optimize the chemistry toward commercially viable alternatives. Chemical synthesis programs in the R&D-based chemical companies, most notably Syngenta and BASF, resulted in the discovery of the first synthetic strobilurins, namely azoxystrobin and kresoxim-methyl, which were subsequently commercialized. A few years later, metominostrobin (Clough and Godfrey, 1998; Hayase *et al.*, 1995), trifloxystrobin (Margot *et al.*, 1998), picoxystrobin (Godwin *et al.*, 2000), and pyraclostrobin (Ammermann *et al.*, 2000) were announced. During the 1990s, famoxadone (Joshi and Sternberg, 1996) and fenamidone (Mercer *et al.*, 1998) were discovered. More recently, pyribencarb (Kataoka *et al.*, 2010) has been announced and described as having the QoI mode of action. Other fungicides expected to be QoIs such as coumoxystrobin, dicloaminostrobin, enoxastrobin, pyrametostrobin, pyraoxystrobin, and triclopyricarb have been recently reported. The various QoI fungicides have very different physicochemical properties, which confer different behaviors in the plant. For example, picoxystrobin is the most rapidly absorbed into plant tissue and the most xylem-systemic (Godwin *et al.*, 2000). Azoxystrobin and metominostrobin are also xylem-systemic. In contrast, kresoxim-methyl (Ammermann *et al.*, 1992), trifloxystrobin, and pyraclostrobin are all nonsystemic.

The QoI fungicides are respiration inhibitors – their fungicidal activity comes from their ability to inhibit mitochondrial respiration by binding at the so-called Qo site (the outer quinol-oxidation site or ubiquinol site) of the cytochrome bc_1 enzyme complex (complex III), located in the inner mitochondrial membrane of fungi and other eukaryotes. This inhibition blocks electron transfer between cytochrome *b* and cytochrome c_1, which, in turn, leads to an energy deficiency in fungal cells that halts reduced nicotinamide adenine dinucleotide (NADH) oxidation and adenosine triphosphate (ATP) synthesis, thereby halting the production of ATP. This leads to the stopping of the energy production and the fungus eventually dies. All the QoI fungicides share this common mode of action. The toxophore is similar in all compounds and always carries a carbonyl oxygen moiety, thought to be responsible for binding.

Following their introduction in 1996, the strobilurins rapidly became widely used in many crops around the world. The reason for this was their revolutionary levels of disease control and financial returns, and also their positive physiological effects in many crops, resulting in greener crops and increased yields. Possibly due to this rapid widespread use, resistance issues arose rather soon in some key diseases. Although in Europe, monitoring of the air spora of *Blumeria graminis* f. sp. *tritici* (wheat powdery mildew) in 1996 and 1997, conducted independently by members of the manufacturing industry, did not reveal the presence of any QoI-resistant strains anywhere across the continent, further monitoring throughout Europe during 1998 revealed the presence, for the first time, of resistant spores in northern Germany. It was reported at the time that the presence of such strains in northern Germany influenced the performance of strobilurins against this wheat powdery mildew in a negative way, and should, therefore, be regarded as field resistance. Since these first occurrences of resistance to the QoI fungicides in cereal powdery mildew, intensive studies across crops and continents have shown many further cases of resistance in key plant diseases to this fungicide group (FRAC, Leadbeater, 2012a). However, despite the rather frequent occurrence of resistance, disease, and resistance management strategies based around mixtures, alternations with other fungicide mode of action groups have been implemented and QoI fungicides remain in widespread use today. This is due in main to their continuing broad-spectrum disease control but also at least, in part, to the additional physiological benefits to crops, which includes increased greening and robust yield benefits (Grossmann and Retzlaff, 1997; Grossmann *et al.*, 1999; Bayles and Hilton, 2000).

SDHI Fungicides

The SDHI fungicides were discovered and introduced more than 40 years ago. These 'first-generation' carboxamides, carboxin, and oxycarboxin, although having limited spectra of disease control (mainly the basiodimycetes – smuts, bunts, and rusts), are systemic and, therefore, generated great interest. They represented a new way to control these economically important plant diseases – the treatment of seeds or plants with these chemicals resulted in higher yields of crops not only because of disease control but also because of growth stimulation. These systemic fungicides may be applied to seed, soil, or plants, but seed application is the most practical for the control of smuts and bunts.

Following the introduction of carboxin and oxycarboxin, structural analogs were introduced such as benodanil and fenfuram, followed by a range of SDHIs (e.g., mepronil, flutolanil, furametpyr, and thifluzamide) in the 1980s and 1990s with a focus on rice diseases. Despite the replacement of the 1,4-oxathiin ring in carboxin by a variety of alternative ring systems (e.g., phenyl-, furan-, pyrazole-, or thiazole-rings), the activity spectrum of these early SDHIs remained limited to basidiomycetes (Glättli *et al.*, 2011). However, further innovation in the chemistry of the SDHIs resulted in the discovery of boscalid, an SDHI with a considerable expansion of its disease control spectrum to various ascomycete fungi. Boscalid was the first member of this fungicidal class to control a broad range of pathogens in fruits, grapes, vegetables, and arable crops such as cereals and canola (Stammler *et al.*, 2007, 2008). This discovery caused renewed interest in this group of fungicides and, as a result, a wave of new compounds have been announced

and are expected to be commercialized over the next few years addressing a wide range of specialty crop and cereal diseases; these include benzovindiflupyr, bixafen, fluopyram, fluxapyroxad, penflufen, penthiopyrad, sedaxane, and isopyrazam.

The target enzyme of SDHIs is succinate dehydrogenase (SDH, so-called complex II in the mitochondrial respiration chain), which is a functional part of the tricarboxylic cycle and linked to the mitochondrial electron transport chain (Keon *et al.*, 1991). SDH consists of four subunits (A, B, C, and D), and the binding site of ubiquinone (and of SDHIs) is formed by the subunits B, C, and D. Inhibition of SDH impacts on the TCA cycle and quickly will reduce energy (ATP) conservation. Inhibition will also generate reactive oxygen species (ROS), which may be one of the primary ways that SDHIs exert their effect. Clearly, inhibition of SDH has a strong impact on growth and development. Although the QoI fungicides and the SDHIs modes of action involve the inhibition of fungal respiration, the two groups act on different parts of the respiration chain and show no cross-resistance. Thus, although there is cross-resistance between all members of the SDHI group of fungicides, there is no cross-resistance between that group and other important groups such as the QoIs. This is very important in terms of resistance management. Resistance has never emerged as a practical problem to the earlier generation of SDHI fungicides, although it can be generated quite easily in the laboratory. However, high levels of resistance to boscalid were selected quite quickly in field populations of 'high-risk' pathogens such as *B. cinerea*, *Corynesporim cassiicola*, and *Alternaria alternata*. These indications of a significant resistance risk to the SDHI fungicides led to an early recognition of the need to implement resistance management strategies to protect the mode of action; it also led to the formation of a FRAC Working Group in 2009, ahead of the introduction to the market of the majority of the new generation of SDHI fungicides. Intensive research and monitoring programs are under way in industry and in various institutes and so far no resistance has been detected in key crop/disease combinations for most crops including cereals. Clearly, however, successful resistance management will be key to ensuring the longevity of this valuable group of broad-spectrum, highly effective fungicides in the market place.

Phenylamides

The first and most significant member of the phenylamides, metalaxyl, was introduced to the market in 1977. Metalaxyl brought a completely new level of control to the oomycete-incited diseases such as late blight, downy mildews, and *Pythium* damping-off, through its systemic properties that offered protection to the plants as seed treatments and soil or foliar applications. Metalaxyl was followed by the other commercial phenylamides (furalaxyl, benalaxyl, oxadixyl, and ofurace). The unique properties of phenylamide fungicides, such as the control of all members of the *Peronosporales* and most Pythiales, the longlasting preventive and curative activity, the high systemic activity, and the excellent safety profile have been reviewed by Gisi and Ziegler (2002) and Müller and Gisi (2012). Phenylamide fungicides especially affect hyphal growth and the formation of haustoria and sporangia in oomycetes (Schwinn and Staub, 1995). In 1996, the commercial introduction of the more active enantiomer of metalaxyl, metalaxyl-M (mefenoxam) was announced. The concept of using chiral phenylamides has also been taken up in the case of benalaxyl-M (kiralaxyl) in 2007.

The phenylamide fungicides inhibit ribosomal RNA synthesis, specifically RNA polymerization (polymerases). In mycelium of *Phytophthora megasperma*, metalaxyl affected the polymerase 1 complex of rRNA synthesis, which was considered as the primary site of action (Davidse, 1988). A secondary site of action was postulated for benalaxyl and the chemically related herbicides propachlor and metolachlor by Gozzo *et al.* (1984) and again for kiralaxyl in 2009. However, this effect on membrane function occurred at much higher fungicide concentrations than those needed for rRNA inhibition, suggesting that it might be an unspecific rather than a primary activity.

Shortly after the commercial introduction of metalaxyl, resistant isolates were detected in *Pseudoperenospora cubensis*, *P. infestans*, *P. tabacina*, and *P. viticola*. In most cases, this was linked to a decline in disease control. As a consequence, strict recommendations for the use of phenylamides were introduced to prevent and further delay resistance evolution. These recommendations support the use of phenylamides for foliar treatment only in mixture with other, low-resistance-risk fungicides such as mancozeb or chlorothalonil, and a restriction in the number of applications. These recommendations have been implemented successfully and products containing mefenoxam and metalaxyl remain important fungicides today, despite the fact that resistant isolates can be found in all regions of the world and on many crops.

Carboxylic Acid Amides

The carboxylic acid amide (CAA) fungicides consists of three subclasses: the cinnamic acid amides (dimethomorph, flumorph, and pyrimorph), the valinamide carbamates (benthiavalicarb, iprovalicarb, and valiphenalate), and the mandelic acid amides (mandipropamid). Dimethomorph was the first to be introduced in 1988, followed by iprovalicarb with flumorph, benthiavalicarb, mandipropamid, valifenalate, and pyrimorph introduced later. The reason these fungicides are classified together is there is a common cross-resistance pattern among all members for the vast majority of tested isolates of *P. viticola*. Other common features are the specific and rather narrow spectrum of activity against oomycetes, including pathogens of the Perenosporales such as *Bremia lactucae* on lettuce, *Perenospora* spp. on tobacco, pea, onions, and other vegetables, *P. viticola* on grapes, *P. infestans* on potatoes and tomatoes and several other *Phytophthora* species on other crops such as peppers and pineapple. However, the entire genus *Pythium* is insensitive as are all other pathogens outside the oomycetes. CAAs inhibit the germination of cystospores and sporangia (but not zoospore release and motility). They affect growth of germ tubes and mycelium, thus preventing infection of the host tissue. The CAAs have differing properties but are largely preventive fungicides, although dimethomorph has curative and antisporulant activities. Some systemic activity is found in some members of the class.

The mode of action of CAA compounds is directly linked to the inhibition of cellulose synthesis in the oomycete plant

pathogens (Blum *et al.*, 2010a). Uptake studies with ^{14}C-labeled mandipropamid showed that this fungicide acts on the cell wall but does not enter the cell. Furthermore, ^{14}C glucose incorporation into cellulose was perturbed in the presence of mandipropamid. Gene sequence analysis of cellulose synthase genes in laboratory mutants insensitive to mandipropamid revealed two point mutations in the cellulose synthase (*PiCesA3*) gene. Both mutations in the *PiCesA3* gene result in a change to the same amino acid (Glycine-1105) in the protein. The transformation and expression of a mutated *CesA3* allele in a sensitive *P. infestans* isolate resulted in a CAA-resistant phenotype. Thus, cellulose synthase can be postulated as the primary target enzyme for CAA activity.

Resistance to the CAA fungicides in *P. infestans* and *B. lactucae* has never been detected in field populations even though dimethomorph has been in use for more than 15 years. Mutants resistant to the CAAs have been produced in the laboratory in *P infestans*, but are found to show reduced growth rates, reduced pathogenicity and reduced fitness. In contrast to this, resistance to CAAs in *P. viticola* have been reported since 1994, shortly after the introduction of CAAs in France. Resistance has increased gradually in European countries over the past few years (www.FRAC.info), and resistance has been reported in *P. cubensis* from sites in USA, Israel, and China. Studies on the inheritance of resistance to the CAA fungicides in *P. viticola* show it to be based on one recessive nuclear gene (Gisi *et al.*, 2007; Blum *et al.*, 2010b). Resistance-management practices have been defined for the CAA fungicides by FRAC with particular concern around the higher-risk pathogens, such as *P. viticola*; these fungicides are recommended to be used only in mixture with multisite fungicides or other effective noncross-resistant partner fungicides and are limited in number during the growing season. In addition, although some CAA fungicides demonstrate some curative activity, they are recommended to be used in a preventative manner. In contrast to this, resistance risk in *P. infestans* to the CAA fungicides seems to be low and, therefore, the most active of these fungicides can be recommended for use without mixture partners. However, as a resistance-management precaution, the number of CAA fungicides is limited to no more than 50% of the treatments against this disease.

Control of Bacterial Plant Pathogens

As has been already mentioned in this article, bacterial diseases of plants present special challenges in terms of their control. In contrast to the wide range of fungicides available for the control of fungal plant diseases, there is a very limited range of options available for the control of bacterial diseases. Probably the most commonly used products for bacterial disease control are based on copper, used either alone or in mixture with an ethylene bisdithiocarbamate fungicide such as mancozeb. The level of disease control given by such products is at the level of suppression at best and therefore they must be supported by the use of tolerant or resistant varieties, clean seed, and other good cultural practices. Bacterial resistance to copper fungicides is quite common, further increasing the challenges for growers to control these diseases.

Another option for the control of bacteria is the use of antibiotics. The classic definition of an antibiotic is a compound produced by a microorganism that inhibits the growth of another microorganism. Antibiotics were introduced into the field of human medicine in the 1950s and were heralded as 'miracle drugs' for the control of human bacterial diseases and infections worldwide, and, indeed, still play a major role in human medicine today. Of the many antibiotics used, only two are commonly used on plants for bacterial disease control: streptomycin and oxytetracycline. For the control of certain bacterial diseases of plants, streptomycin was indeed a silver bullet. Unfortunately, just as the emergence of bacterial strains resistant to antibiotics has limited their performance in clinical settings, streptomycin resistance has destabilized plant bacterial disease control. The antibiotic resistance crisis in medicine has been widely publicized and is recognized as a major threat to controlling human bacterial diseases and infections worldwide (Levy, 1998). Efforts to conserve the efficacy of antibiotics in medicine have drawn scrutiny to all antibiotic use within and outside the medical field, including agriculture. For this reason, the use of antibiotics in horticulture and agriculture is not permitted in many countries of the world. There are exceptions to this, such as the United States.

Streptomycin is an aminoglycoside antibiotic. Oxytetracycline is a member of the tetracycline antibiotics. Both streptomycin and oxytetracycline inhibit protein synthesis by binding reversibly to bacterial ribosomes. In the United States, streptomycin use is registered on 12 plant species, but the primary uses are on apple, pear, and related ornamental trees for the control of fire blight caused by *E. amylovora*. Oxytetracyline is used in the USA primarily on peach, nectarine, and pear. It is also used on an emergency basis on apple in specific regions where streptomycin-resistant strains of *E. amylovora* have been documented. Antibiotics provide a protective barrier on the surface of plants that suppresses the growth of the pathogen before infection. Streptomycin has been the antibiotic of choice for fire blight as it kills the pathogen on the plant surface. Oxytetracycline, which reduces the growth rate of the pathogen but does not kill existing populations, is less effective than streptomycin. Tetracycline derivatives are the only antibiotics that are registered for internal use in plants. They are injected into the trunks of palm and elm trees to treat lethal yellows diseases caused by phytoplasmas. This is, however, a labor-intensive and expensive process. Antibiotic injections are practical only for isolated high-value ornamental trees and not vast plantings of agricultural or forest trees. The efficacy of antibiotics for the control of plant diseases has been diminished in some regions due to the emergence of antibiotic-resistant strains of pathogens. However, until effective and economic alternatives become available, antibiotics will remain important tools for the management of some of the most devastating plant diseases.

Control, or suppression, of bacterial diseases of plants can also be achieved by using the natural defense mechanisms of plants and switching them on, or enhancing them, by the use of host defense inducers. Two major types of induced resistance have been identified: systemic acquired resistance (SAR), which depends on salicylic acid (SA); and induced systemic resistance (ISR), which requires jasmonic acid (JA) and ethylene, but not SA. Typically, in nature, SAR is induced by a

limited primary infection caused by a necrotizing pathogen, whereas ISR is induced by nonpathogenic organisms that colonize the roots. Both SAR and ISR confer an enhanced defense capacity. These mechanisms can be triggered in plants by numerous fungi and bacteria, and can also be effectively triggered by the use of a number of synthetic chemicals. The main commercial chemical compounds available so far are inducers of SAR – these products can be shown to have no direct antifungal or antibacterial effect when used *in vitro*, but in combination with a host plant, clearly induce the host plant's natural defense mechanisms to confer protection against pathogenic fungi and bacteria. The level of control of fungal diseases by induced-resistance products is usually significantly less than that achieved by an effective modern fungicide and is usually more complicated because such products must be applied in advance of infection to allow the plant time to activate its defense mechanisms. But in the case of bacterial disease control, where the effectiveness of the available products is often already rather low, resistance-inducing chemicals can offer a good alternative. An additional advantage of induced-resistance compounds is that, due to their unique and rather nonspecific modes of action, the risk of resistance occurring against them seems to be low, which means their effectiveness should be maintained for the future.

Examples of bacterial disease control by induced resistance compounds used commercially are probenazole, tiadinil, and isotianil used in Asia, mainly to control fungal blast disease and bacterial blight in rice. ASM induces a broad resistance spectrum on an extended diversity of dicotyledonous and monocotyledonous plants. It is used as a foliar spray and as a seed treatment in various dicotyledonous crops for the control of a range of diseases, including plant pathogenic bacteria. ASM is, today, successfully registered and sold worldwide in a wide range of crops, including tomatoes, tobacco, pears, bananas, lettuce and other leafy vegetables, nuts, and cucurbits.

Fungicide Resistance and Its Management

Fungicide resistance is the naturally occurring, inheritable adjustment in the ability of individuals in a population to survive a plant-protection product treatment that would normally give effective control (OEPP/EPPO, 1999). Although resistance can often be demonstrated in the laboratory (and is, indeed, an important part of resistance-risk assessment for new fungicides), this does not necessarily mean that disease control in the field is reduced. 'Practical resistance' is the term used for the loss of field control due to a shift in the pathogen's sensitivity to a fungicide. When it occurs in the field, fungicide resistance affects all those concerned with crop health; the growers, advisors, and the industry that provides these with the advice and products necessary to ensure a healthy, productive crop. Without successful resistance management, the effectiveness and eventually the number of modern fungicides available to the farmer and grower will diminish rapidly, leading to poor yields and reduced crop quality. Such a scenario could quickly lead to overuse of affected fungicides as users strive to get products to work (e.g., higher dose rates being used, or an increase in the frequency of application), leading in turn to increased and undesirable loading on the environment.

Growers and the agrochemical industry have lived with resistance problems for many years. Resistance was not considered to be a real problem in the early 1960s – fungicides had been used over many years, quite intensively in several crops, with no obvious signs of problems. At that time, the fungicide market consisted largely of nonsite-specific, nonsystemic, and moderately effective fungicides. There were some reports of resistance to diphenyl and sodium-*o*-phenylphenate in *Penicillium digitatum* in citrus at that time (Harding, 1962), and a failure of hexachlorbenzene to control *Tilletia foetida* in Australia (Kuiper, 1965); in addition, some isolates of *Pyrenophora avenae* in oats in Scotland were found to be resistant to organomercurial seed treatment (Noble *et al.*, 1966), but these were a small number of cases and were not considered to be very economically significant. Moreover, the fungicides had been in use for many years and so were not considered to have important consequences in terms of relevance to other fungicide and disease combinations.

However, the cases of practical resistance to the benzimidazole fungicide benomyl after only 2 years of commercial use in the USA on cucurbit powdery mildew caused far more concern (Schroeder and Provvidenti, 1969). Other reports of resistance to benomyl and other related fungicides followed quite quickly afterward. Reports of resistance to fungicides became more frequent following these early cases and, in the 1970s, reports were published documenting resistance to important fungicides such as dodine, kasugamycin, and the phenyltins. Since the 1970s, cases of resistance to fungicides have increased in number, significance, and geographical spread, with the phenylamides, dicarboximides, SMIs (e.g., triazoles), QoIs (e.g., strobilurins), and, more recently, the SDHIs all suffering from to shifts in sensitivity or full practical resistance in key crops and diseases.

From the above, it can be easily realized that fungicide resistance is a real threat to the effectiveness of many fungicide groups and must be managed, to ensure good product performance in the field for the grower and also to justify sustainable investment by the agrochemical industry into new fungicides. Fortunately, despite a general widespread occurrence of resistance to several fungicides, effective management strategies have limited the impact of this on crop protection and production. Fungicide resistance has been much researched and with the expert knowledge that such research has provided, effective resistance management strategies have been developed and implemented. Because the risk of the impact of resistance being high is directly related to the degree of exposure of the plant pathogen to a fungicide (or a group of fungicides belonging to the same cross-resistance group as defined by FRAC), most resistance management strategies involve limiting the number of applications of the 'at-risk' fungicide in a disease-control program. The other fungicides used in the disease control program must have different modes of action to the fungicide in consideration. Other fundamentals of resistance management include the use of mixtures of fungicides from different cross-resistance groups to avoid reliance on a single mode of action, starting the fungicide spray program early in disease epidemics (to reduce the probability that a chance mutation conferring resistance has happened in

Table 4 Resistance risk classification of fungicides according to the Fungicide Resistance Action Committee (FRAC) Code List 2012[a]

Resistance risk classification	*Number of fungicide groups (FRAC code list)*	*Number of fungicides*	*Worldwide sales 2011[a] (US$×1000)[b]*
High	4	30	4 041
High to medium	4	24	836
Medium	8	51	3 868
Medium to low	11	36	1 269
Low	11	23	2 348
Not known	19	32	718
Others (bactericides, etc.)			225
Total	57	196	13 305

the fungal population) and to avoid long persistence of a single 'at-risk' fungicide in a crop such as might be experienced by a soil application targeted to control foliar disease in the crop. It is clear from these basic principles of fungicide resistance management that there is a high requirement for many fungicides with different modes of action to be available for the grower to choose from, which includes the preservation in the market place of the older modes of action such as multisites, which have a low resistance risk (Leadbeater *et al.*, 2008; Leadbeater, 2011). The importance of fungicide resistance management becomes more clear when the fungicide market is considered. In 2011, considering the highest selling fungicides and their classes, 62% of the world fungicide market (by value) consisted of only six single-site modes of action (**Table 3**). These six mode-of-action groups are the QoIs, the azoles, benzimidazoles, SDHIs, phenylamides, and amines. Of these six, five are classified by FRAC as high risk or between medium and high risk of resistance occurring. Only 18% fall into the category of low resistance risk (23% if 'resistance not known' fungicides are included; **Table 4**). These statistics do not give the complete picture with regard to treated areas with each mode of action of course, but show clearly what fungicides growers depend on most to provide disease control.

In recognition of the challenge set by the possibility of fungicide resistance developing., and with the experiences of the benzimidazoles and phenylamides, FRAC was formed following a course in resistance in 1980 and a subsequent seminar in Brussels in 1981; FRAC is still extremely active today (Leadbeater, 2012b, www.FRAC.info). The purpose of FRAC is to provide fungicide resistance management guidelines to prolong the effectiveness of 'at-risk' fungicides and to limit crop losses should resistance occur. FRAC members are recognized industry experts in the field of fungicide resistance and are actively engaged in scientific work and discussions and are frequent contributors at educational events such as scientific symposia and symposia. Important resources have been produced by FRAC and are available on the FRAC website, including educational monographs, sensitivity testing methods, classification tables of fungicide mode of action grouping, summaries of records of fungicide resistance cases, and much more. Importantly, the updated situation with regard to resistance to the most important groups of 'at-risk' fungicides is available on the website for consultation and downloading. FRAC does not work in isolation, of course, and the key is cooperation and consultation between FRAC members and researchers, consultants, advisors, and officials in public and private organizations in order to share scientific information and enable all to come to common, supported conclusions, practical advice, and recommendations.

The Future

As discussed already in this article, the costs of discovery and development of new fungicides are continuing to escalate; at the same time the hurdles with regard to registration are increasing. These two driving forces have some obvious consequences for the future. Because of the increasing costs of development and registration, to justify the development of new fungicides they will need to have a large business potential to enable industry to recoup the costs of R&D. This drives product design toward broad-spectrum disease control products on a wide range of crops. However, to realize the full business potential of the new fungicide, it must be able to be registered! This has, of course, always been the case in new product development but tighter requirements will lead in the future to a different approach where the ability to register a new fungicide takes priority over potency and the absolute level of disease control. Hopefully, however, future innovation will be high enough to deliver highly effective products that can be successfully commercialized. These requirements are likely to continue to drive the current trend in the increase of biologicals and biofungicides in the market. Biofungicides, while themselves having some specific technical challenges such as production capacities and consistency, shelf life, and level of performance, and so on, have some advantages of reduced data required for registration (therefore, lower costs), lower likelihood of residues in produce plus the probability of lower resistance risk than a conventional (single-site) fungicide. In the future, therefore, biofungicides are likely to be more successful not only in providing solutions for organic farming but also as integrated elements of successful disease management programs in combination with conventional chemical fungicides. Biofungicides will be especially useful when used close to crop harvest because they are not likely to leave undesirable residues on and in food.

In terms of innovation in conventional fungicides, this is difficult to predict. Clearly, the focus will be on new modes of action in order to overcome current resistance problems, plus the invention of new chemicals that themselves have low

resistance risk. As discussed in the Section Challenges for Developing Chemical Agents for Plant Disease Control, this is a great challenge because 'designing' new modes of action is difficult and the additional requirement of low resistance risk presents an even higher challenge to even be able to determine this when novel chemistry has been found. The current wave of new fungicides of high potential market significance depends greatly on a single mode of action (the SDHI fungicides), mainly because this class of chemicals clearly has a high potential for innovation in structure and disease-control spectrum. However, with a high number of new, potent fungicides entering the market at approximately the same time into the same crops and targets, resistance management will be a particular challenge. With this challenge in mind, FRAC established a specific Working Group for the SDHI fungicides early, and before the market introduction of most of the 'new generation SDHI' fungicides. Hopefully, this approach will result in success in managing resistance in this group of important fungicides.

Beyond the SDHI fungicides, it is difficult to see the next wave of innovative fungicides. Several new active ingredients are announced to be introduced over the next few years, but with few exceptions such as tiadinil, fenpyrazamine, they are mainly further SDHIs. However, it is difficult to be definitive because agrochemical company pipelines are confidential and only limited information can be obtained, for example, by monitoring patents. It can be assumed that at any point in time there is much more in company pipelines than is in the public domain, and although it is increasingly challenging to find truly new modes of action, history has shown that industry is very successful in responding to this challenge in fungicides.

Conclusion

Despite the enormous efforts of research and development into the control of plant diseases over the past decade, crop losses to destructive plant pathogens such as the fungi, oomycetes, and bacteria remain high and are among the most limiting constraints to crop yields worldwide. Current best practice for the control or limitation of plant diseases of crops includes good crop hygiene and cultivation methods, the selection of disease resistant or tolerant varieties, good agricultural practices such as planting times, fertilizer regimes, and the use of effective chemical fungicides. Since the days of the early synthetic chemical fungicides, great advances have been made by science and the chemical industry in inventing and developing lower use-rate fungicides that are safer to humans and the environment. The improved physical and chemical/biochemical characteristics of these modern fungicides has enabled growers to far more effectively control the diseases in their crops. Properties such as systemic activity, curativity, longer duration of control, and improved rain-fastness have enabled the use of novel application technologies (e.g., seed, soil treatment, application in irrigation systems) and have resulted in more flexibility and labor saving for growers worldwide. It is a fact that yield and quality in many crops would be extremely low without the use of modern fungicides and, in some extreme cases, production would today be impossible without their use (e.g., potato late blight, Asian soy rust in Brazil). It is for these reasons that, despite significant increases in the costs and other hurdles involved in the R&D of new crop protection products to the market, the agrochemical industry continues to invest into the invention and development of new chemical fungicides to meet the demanding needs of economic disease control in the modern world.

Experience has shown, however, that chemical fungicides must be used responsibly and in an integrated way with other crop-protection practices to ensure effective disease management for the long term. It can be quite clearly seen from this article that fungicide resistance is a constant threat, particularly to the modern, single-site inhibitors, which must always be considered and addressed in the development of any new fungicide product. The invention of highly effective, highly specific fungicides carries a special risk of resistance development – these often becoming the victims of their own commercial success. It is important that a full evaluation of the resistance risk is made before the commercial introduction of any new fungicide, with management strategies put into place from the start to prolong the effective life of the fungicide(s) in question. Scientific knowledge has progressed tremendously over recent years to enable such risk assessment. It is equally clear that, despite the significant scientific advances in fungicide technologies in recent years, there remains a very important role for the older fungicides, especially those with nonspecific modes of action such as the 'multisite' fungicides, which have a low risk of resistance occurring and, therefore, are valuable to be used in combination with the newer modes of action. There remains a high requirement for diversity in chemistry and in modes of action to ensure the future success of chemical fungicides. It is hoped that, in the future, the next generations of fungicides invented by the agrochemical industry will include novel modes of action, a low risk of resistance, and continuing trends toward even greater safety to crop, humans, and the environment.

Plant Health Management: Herbicides

IC Burke, Washington State University, Pullman, WA, USA
JL Bell, Dow AgroSciences, Indianapolis, IN, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Herbicide Any chemical substance or cultured biological organism used to control or suppress plant growth.
Mechanism of action The primary biochemical or biophysical event that the herbicide directly affects.
Mode of action Refers to the entire sequence of events from the introduction of a herbicide into the environment to the death of the plant.
Postemergence Herbicide-application timing targeting weeds that have emerged from the soil.
Preemergence Herbicide-application timing targeting weeds that have not germinated.
Safener A herbicide safener, also termed antidote, antagonist and protectant, is a compound applied to a crop that confers a selective advantage to the crop, lending protection from herbicidal phytotoxic effects without reducing activity in target weed species.
Selectivity A selective herbicide is one that is significantly more toxic to some plants than others within the limits of a specified dosage range, the method of herbicide application, and environmental conditions that follow application.

Introduction

The use of chemicals to control weeds dates back centuries – the use of salt is a prime example of humans using a chemical to manage vegetation. The rigorous use of salts and acids in the nineteenth and early twentieth centuries presaged the development of the selective herbicide, as pesticides that control weeds are known. The modern selective herbicide was born in the early 1940s with the discovery of 2,4-D (2,4-dichlorophenoxyacetic acid) and other synthetic plant growth regulators. The use of 2,4-D as a selective herbicide began the modern era of modern weed management. Since that time, significant advances in herbicide chemistry have delivered multiple herbicide classes that interact with a discrete set of plant processes. The use of herbicides has also significantly changed the farming practices on a global basis – in general, herbicide use results in a reduction in rotational diversity by facilitating the repetitive production of crops of high value.

Herbicide has been defined as any chemical substance or cultured biological organism used to control or suppress plant growth. Herbicides are the most commonly utilized crop-protection compounds in the world. In 2007, worldwide herbicide use was estimated at 951 000 MT. Usage in the United States was estimated at 241 000 MT, or 47% of the total pesticide used in the country (Grube *et al.*, 2011). The total annual amount of herbicide use has not changed in the United States over the past 20 years (Figure 1). Rather, there has been a substantial increase in the use of a single herbicide, glyphosate.

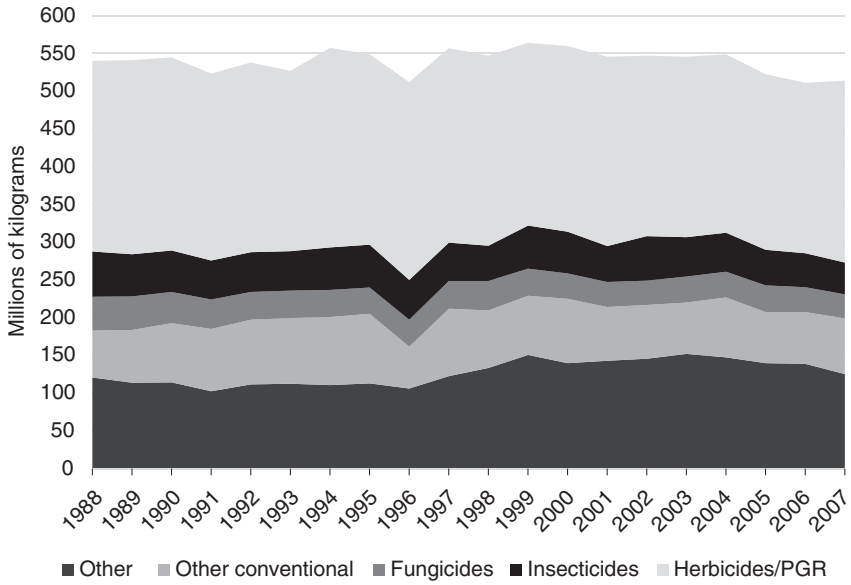

Figure 1 The annual amount of pesticide-active ingredient used in the United States by pesticide type, 1988–2007 estimates in all market sectors. Reproduced from Grube, A., Donaldson, D., Kiely, T., Wu, L., 2011. Pesticides Industry Sales and Usage: 2006 and 2007 Market Estimates. Washington, DC: U.S. Environmental Protection Agency.

Of the top ten pesticides used in the United States, six are herbicides (Grube *et al.*, 2011).

Herbicides are first a labor-reduction tool. Selective herbicides have radically reduced the amount of labor required to manage weeds in crops. Herbicides have also facilitated the adoption of reduced tillage and tillageless (no-till) production systems and weed control in closely seeded crops by controlling weeds within the row. Cultivation, even the most advanced robotic systems, still have difficulty controlling weeds in the crop row. Herbicides also facilitate early planting of crops under adverse soil moisture conditions – tillage often fails to control vegetation when sufficient soil moisture is present to facilitate rerooting. Herbicides offer considerable increases in efficiency compared to human labor inputs. Where labor is scarce or expensive, herbicides offer an efficient, albeit energy-intensive alternative. Where energy inputs have been compared, labor and herbicides are very similar. Ultimately, there is no comparison in terms of cost – herbicides enable far fewer humans to weed much larger areas for about the same energy input and much lower labor costs.

The primary negative attribute of herbicides is a side effect of the beneficial effects. Often, there is a tendency among practitioners to expect a herbicide solution for all weed problems rather than to seek a solution within the framework of the entire production system. There is also a misconception that herbicides offer a complete solution, that there will always be complete control. Such a misconception, coupled with significant selection pressure imposed by the use of herbicides and with marketing and supply chain aspects, has led to widespread herbicide resistance and shifts in weed species composition. A second negative aspect of herbicides is their use necessitates a diminishment of agricultural diversity – they are well suited to the monoculture cropping systems of the twentieth and twenty-first century. Of course there are other primary negative aspects of herbicides and herbicide use. The most common problems associated with herbicides include injury to crops, injury to nontarget vegetation, and herbicide residues persisting in the soil and injuring crops grown in rotation. Less common problems can include effects on nontarget organisms, including fish, although such problems are usually related to applicator error rather than the herbicides themselves. In rare circumstances, high levels of use can couple with less than ideal environmental profiles to result in groundwater contamination and other unanticipated effects.

Since the 1940s, foreign and domestic agrochemical companies have commercialized several hundred herbicide active ingredients. Today there are more than 130 chemical compounds worldwide that are used as selective herbicides and approximately 30 others that are used as nonselective herbicides. In contrast, there are many hundreds of trademarked herbicide products commercially available as there may be more than one manufacturer of a particular herbicide or multiple formulations that contain the same active ingredient. As most herbicides are applied in mixtures containing two or more herbicides, the list of possible herbicide combinations becomes quite extensive as does the knowledge to use such mixtures. As a consequence, there are multiple names associated with herbicides. The active ingredient is the chemical in a herbicide formulation responsible for phytotoxicity and has a chemical name according to the rules of nomenclature of the International Union of Pure and Applied Chemistry. Each herbicidal chemical has one common name that is usually a simplified version of the chemical name. An appropriate authority must approve common names before being accepted by working weed scientists. Authorities include the American National Standards Institute, the Weed Science Society of America, and British Standards Institution. However, growers typically use a trade name by which a commercial product is identified that may contain one or more herbicidal active ingredients.

Selectivity of Herbicides

Selectivity is the most important factor for successful herbicide application – success being defined as the death of the weeds and not the crop. A selective herbicide is one that is significantly more toxic to some plants than others within the limits of a specified dosage range, the method of herbicide application, and environmental conditions that follow application (Harrison and Loux, 1995). Herbicide selectivity is the foundation of successful chemical weed management and is conferred by physical or physiological factors that produce differential herbicide toxicity for crops and weeds (Harrison and Loux, 1995).

Physical factors that confer selectivity by application method significantly reduce or eliminate exposure of the crop plant to the herbicide, and include differential placement or differential absorption. Differential translocation, enzyme target-site resistance, or differential metabolism of the herbicide confers biological selectivity. Selectivity of herbicides among crop plants is usually attributable to a single mechanism – primarily differential metabolism. Often a combination of application method and biological tolerance is required to impart the greatest degree of selectivity over a range of herbicide dosages and environmental conditions (Harrison and Loux, 1995). Virtually all herbicides lose selectivity if applied improperly or under environmental conditions that adversely affect physiological tolerance mechanisms.

Physical placement of the herbicide can achieve significant selectivity. Application of herbicides used for selective control of small-seeded grass and broadleaf weeds in large-seeded annual crops to the soil surface following planting is one example of selectivity by placement. Selectivity is achieved when seeds are positioned in the soil beneath the zone of greatest herbicide concentration where the smaller-seeded weeds are germinating. Directed postemergence sprayers, shielded sprayers, rope-wick applicators, and other specialized herbicide-application equipment that direct herbicide applications on weeds and away from crop plants are examples of herbicide-application selectivity by placement (Harrison and Loux, 1995). Environmental factors such as soil type or moisture availability can modify the selectivity by placement, as can biological factors such woody tissue or root zone development.

Selectivity conferred by differential absorption of herbicides by different plant species is not common, largely due to the effective array of adjuvants designed to aid penetration. When selectivity is conferred by differential absorption, it is based on leaf cuticle thickness and composition. However,

cuticle thickness can vary from plant to plant and even among leaves of the same plant, as cuticle formation depends on environmental conditions. Not surprisingly, plants with thickened cuticles or leaf pubescence are more difficult to control with most foliar-applied herbicides. Adequate soil moisture, sunlight, and high relative humidity are more conducive to penetration by herbicides. Drought or prolonged periods of hot, dry weather can result in an increase in epicuticular wax, cuticle dehydration, and plant stress, and foliar application of herbicides during such periods may result in a loss of effectiveness due to lack of herbicide absorption (Harrison and Loux, 1995).

Once across the cuticle barrier, herbicides are translocated in the apoplast or symplast some distance before reaching their biochemical site of action. Herbicides first undergo short-distance translocation from the epidermis to the vascular tissue. Even during the short transport period, those herbicides moved in the symplast are likely to have substantial effects on the cells they have entered. In foliar tissue, herbicide moves to the xylem or phloem via normal apoplastic or symplastic routes. Herbicides translocated short distances in the root apoplast that are traveling toward the xylem and phloem in the center of the root encounter and must cross the endodermis. Finally, herbicides that cause membrane disruption usually do not translocate appreciably except under special circumstances.

Transport of herbicides (and pesticides in general) is an important criterion and several models have been developed to describe and predict mobility (Hsu and Kleier, 1996; Satchivi *et al.*, 2006 and related citations). Herbicide translocation is dependent on the chemical properties of the herbicide and conditions within the plant. Some herbicides, for example, may undergo reactions on entering into the symplast resulting in anionic or more polar forms of the herbicide that cannot return to the cell membrane. The herbicide is thus 'trapped' in the cytoplasm and is largely confined to translocation in the symplast (Harrison and Loux, 1995). Conversely, nonionic herbicides that move freely across cell membranes and into and out of living cells undergo translocation primarily in the apoplast. Differential rates and extent of translocation sometimes play an important role in determining herbicide selectivity among plants.

The driving force behind apoplastic translocation is transpiration – net movement of apoplastically translocated herbicides in plants is upward from site of entry along the gradient from highest water potential (soil solution or soil water) to lowest water potential (the atmosphere) via the transpiration stream. As a result, apoplastically translocated herbicides are generally soil-applied or require complete coverage of above-ground structures (Harrison and Loux, 1995). In contrast, herbicide movement via the symplast is bidirectional, with direction of movement dependent on the location of areas of greatest assimilation supply and demand within the plant. Photosynthate source and sink relationships determine the rate, direction, and extent of phloem-mobile herbicide translocation and can change spatially and temporally. Perennial weed source–sink relationships are more complex than that of annuals, and response to phloem-mobile, symplastically translocated herbicides is highly dependent on stage of development. Because a key objective in perennial weed management is to destroy overwintering vegetative propagules (e.g., rhizomes, stolons, tubers, etc.) as well as the foliage, phloem-mobile herbicides should be applied based on knowledge of movement to the vegetative reproductive structures.

Herbicide Metabolism

The most common mechanism that confers herbicide selectivity is differential metabolism – rapid metabolism by the crop and little to no metabolism by the weed. Plants are immobile organisms that must adapt to the environmental conditions where they occur. That environment may include exposure to natural and synthetic toxins such as heavy metals, allelochemicals, pollutants, and herbicides (Riechers *et al.*, 2010). A plant that is tolerant to a herbicide through metabolism is capable of altering or degrading the chemical structure of a herbicide through enzymatic and nonenzymatic reactions that render the herbicide nontoxic (Harrison and Loux, 1995). The rate, in addition to the extent of herbicide metabolism, is also an important factor in determining selectivity. Herbicides often undergo biotransformations in plants and can be metabolically deactivated or metabolically activated. Some herbicides are stable in plant systems, although this is not common. The herbicidal detoxifying metabolic processes include the action of several enzymes (Kreuz *et al.*, 1996). The metabolic processes are divided into three distinct phases. Phase I metabolism involves oxidation by cytochrome P450 monoxygenases and hydrolysis by carboxyesterases. As a consequence of oxidation or hydrolysis, herbicide molecules are susceptible to phase II metabolism, including conjugation to glucose (Hatzios and Burgos, 2004) and glutathione (Edwards *et al.*, 2000; Riechers *et al.*, 1997). Conjugation of herbicide not only modifies the physical properties of the molecule, decreasing the ability to interact with the target site, but also enhances transport by multidrug resistance-associated protein to the vacuole, resulting in a sequestering of the molecule in phase III metabolism (Martinoia *et al.*, 1993; Zhang *et al.*, 2007).

Selectivity can also be achieved by the use of herbicide safeners. An herbicide safener, also termed antidote, antagonist and protectant, is a compound applied to a crop that confers a selective advantage to the crop, lending protection from herbicidal phytotoxic effects without reducing activity in target weed species. Many herbicides are developed for their crop selectivity; however, selectivity is often borderline prohibiting their use or diminishing acceptable weed control rates if not for the safener application (Rosinger *et al.*, 2012). Safeners may be used to overcome injury due to damaging residual pesticide levels allowing for more crop rotational flexibility, or in botanically related minor crops not targeted for product development (Davies, 2001). To date, all commercialized safeners have been developed for major crop species, all of which are monocots (maize, sorghum, rice, and cereals such as wheat and barley). Dicot crops have yet to respond to safener treatments. The method of application has evolved from compounds designed for seed treatments to preemergence mixtures and now postemergence safener-herbicide mixtures. Herbicide safeners act by reducing the

ability of a herbicidal compound to reach its active site mainly by stimulating metabolic processes described previously that alter or sequester the active molecule. Other studied safener-herbicide antagonism mechanisms, including reduced absorption and translocation or completion with the active site, have yielded conflicting results (Davies, 2001; Abu-Qare and Duncan, 2002). Herbicide safeners continue to be of value in agro chemistry. Further elucidation of the processes involved in safener-herbicide detoxification in combination with transgene technologies could increase their utility, especially in dicot crop species (Riechers *et al.*, 2010).

Fate of Herbicides

Fate of herbicides constitutes a topic of its own and will only be reviewed briefly here. The major processes that determine the fate of herbicide in soil are adsorption, transport, and degradation. In principle, all three processes occur once a herbicide is introduced to a soil system. However, there is usually a primary process that determines fate, and the primary process is determined by a multitude of abiotic and biotic conditions in addition to the chemical nature of the herbicide itself. There are excellent reviews on the subject addressing tillage (Alletto *et al.*, 2010), leaching (Flury, 1996), runoff (Wauchope, 1978), volatilization (Taylor and Spencer, 1990), and microbial degradation (Aislabie and Lloyd-Jones, 1995). An excellent introduction and overview is provided by Ross and Lembi (2009) (**Figure 2**).

Adsorption of herbicide governs herbicide fate to a greater extent than the other two processes. Adsorption is defined as the adhesion of molecules to the surface of solids (Ross and Lembi, 2009). Herbicide availability in the soil water fraction depends on the amount of water present, the chemical nature of the herbicide, and the colloidal composition of the soil. Herbicides vary significantly in their chemical properties, and are most commonly weak acids or bases. Depending on pH, such herbicides can ionize and bind tightly to soil particles, rendering them unavailable for absorption by plants. Herbicide solubility can also dictate the amount available in the soil–water fraction, as herbicides with relatively low solubility are usually adsorbed to soil particles and division into the soil–water fraction is based on solubility. Clay and organic matter particles are active colloids in soil, and as the fraction of soil composed of either clay or organic matter increases, adsorption usually increases.

Herbicide movement is largely governed by water movement or by volatilization of the herbicide. They can also be moved away from the site of application in plant material or adsorbed to soil particles. Water movement in soil is complex and can be categorized into three main types: runoff, leaching, and diffusion through capillary action. Runoff and soil-particle movement usually occurs during periods of heavy precipitation on unprotected soils. Leaching, or the movement of herbicide downward in soils with water, is of considerable concern and leaching potential is governed by the affinity of the herbicide to bind to soil and degradation pathway. Movement by capillary action is often upward in the soil, and occurs in areas where irrigation or stored soil moisture occur with low relative humidity.

Herbicides degrade in the environment. The degradation rate of herbicides can be quite variable and are dependent on abiotic and biotic conditions for some time after application. Biotic degradation pathways involve microbial degradation by an array of enzyme-mediated reactions, whereas abiotic degradation is largely attributed to photolysis and hydrolysis. Degradation is governed by adsorption, and herbicides do not

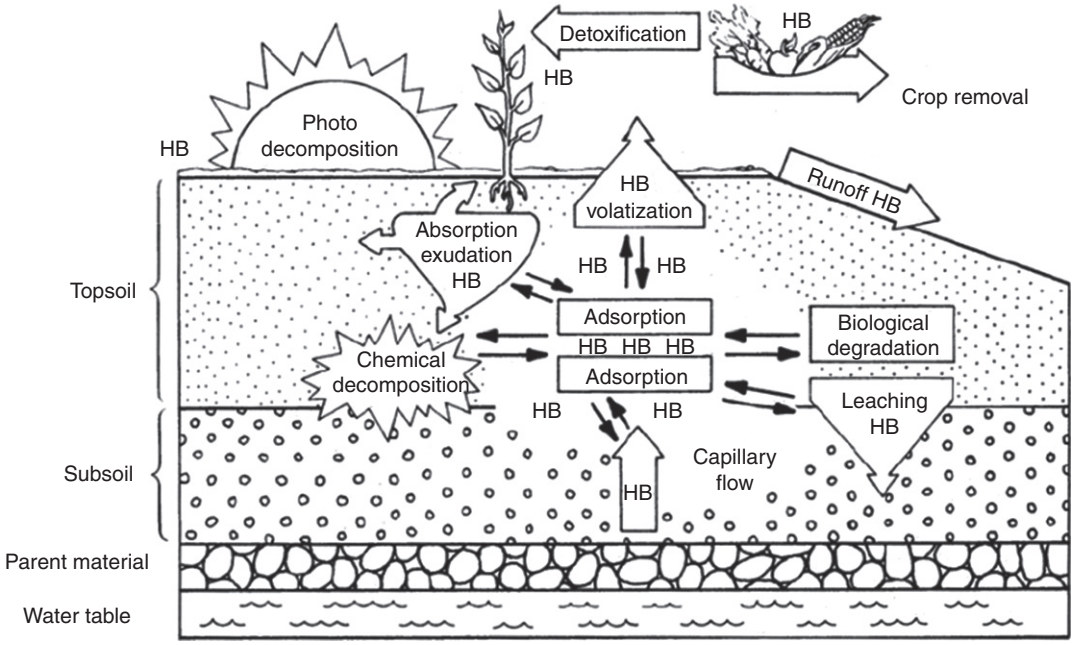

Figure 2 The three primary processes, adsorption, transport, and degredation, that determine the fate of herbicides (HB) in the environment. Reproduced from Ross and Lembi (2009), redrawn from Weber *et al.* (1973).

degrade appreciably when adsorbed to soil particles. Herbicide persistence can be a considerable problem when degradation is slowed by a lack of moisture or temperature to facilitate the reactions, combined with herbicidal activity at very low concentrations.

Herbicide Resistance Action Committee Classification of Herbicides

Herbicides are grouped using a host of attributes. The most common method is by herbicide mode and mechanism of action (the Herbicide Resistance Action Committee (HRAC) and the Weed Science Society of America classification schemes are two examples, (**Table 1**)). Mode of action refers to the entire sequence of events from the introduction of a herbicide into the environment to the death of the plant. The mechanism of action is the primary biochemical or biophysical event that the herbicide directly affects (Monaco *et al.*, 2002). The HRAC proposed a classification system for herbicides according to their enzyme target sites, the similarity of symptoms, or their chemical class (**Table 1**; Menne and Köcher, 2012) and that system will be used here and noted at the beginning of each herbicide mode of action section. Herbicides could be classified by their chemical family, persistence, selectivity, application method, or a host of other attributes. Classifying them by mode of action facilitates communication about risk of herbicide resistance development, as development of resistance can confer cross resistance within a mode of action. Herbicide resistance much more rarely confers resistance across modes of action. Interestingly, a herbicide with a novel or new mode of action has not been introduced since the 4-hydroxyphenylpyruvate dioxygenase (HPPD) inhibitors in the early 1990s. Finally, the modes of action presented here are those for which there are identifiable registered herbicides targeting them – there are a much larger number of target sites for which there is no corresponding registered herbicide.

Acetyl-CoA Carboxylase Inhibitors (Group A)

Acetyl-CoA Carboxylase inhibitors (ACCase; EC 6.4.1.2) are one of the most important modes of action globally, with annual sales estimated to exceed US$1 billion. There are three distinct classes of ACCase inhibitors. The aryloxyphenoxypropionate (AOPP or fop) and cyclohexanedione (CHD or dim) were first identified in the early 1970s, whereas the single member of the 2-aryl-1,3-dione class, pinoxaden, was introduced in 2006. The ACCase inhibitors are widely used in dicotyledonous crops to control grass weeds, and several are used for selective control of grasses in cereals and rice (Hirai, 2002; Hock *et al.*, 1995).

ACCase is a biotin-dependent carboxylase that produces malonyl-CoA from bicarbonate as a source of carboxyl group, and adenosine triphosphate (ATP) as a source of energy. ACCase catalyzes the conversion of acetyl-CoA into malonyl-CoA through the incorporation of a carboxyl group into the acetyl radical of acetyl-CoA. The ACCase herbicides are known to inhibit the carboxylate transferase function of homomeric ACCase found in the plastids of grasses (Hirai, 2002; Menne and Köcher, 2012; Nicolau *et al.*, 2003). These herbicides have specific activity against grass species only – dicots and nongrass monocots are tolerant. Nongrass monocots and dicots have a prokaryotic-type multisubunit plastidial ACCase that is resistant to ACCase inhibitors, as are the eukaryote ACCases from animals and yeast. The transcarboxylation reaction is performed following the two-step process utilized by all biotin-dependent transcarboxylases. Grasses of the Poaceae family contain two eukaryotic-type ACCases – one chloroplastic and one cytosolic. Almost all other plants contain the two well-differentiated forms – a cytosolic eukaryotic-type ACCase and chloroplastic prokaryotic-type ACCase. ACCase inhibitors are complex and often exist as multiple isomers. In the case of the AOPPs, the (*R*)-enantiomer is the most active isomer. CHDs are chiral around a double bond, and the (*E*)-enatiomer is the most biologically active form (Nestler and Bieringer, 1980). As a consequence, products are often reintroduced with formulations containing only the active isomer.

Many studies on the mechanism of action of the ACCase herbicides have been conducted. Nearly all ACCase inhibitors are rapidly absorbed through the cuticle and into leaf cells of both grass and dicot species, where some, particularly the AOPPs, are metabolically activated from esters to acids. The acid is then translocated to meristematic areas of the shoots and roots. The amount translocated is low in relation to the amount applied; however, translocation occurs in both the xylem and the phloem. No significant differences in absorption, translocation, or metabolism of these herbicide, have been reported between dicot and grass species.

Some of these herbicides have soil activity (Gerwick *et al.*, 1988); however, the main activity occurs after postemergence application to emerged grasses. Activity occurs on both annual and perennial grass species, but activity can vary depending on the particular herbicide. Translocation of ACCase herbicides can occur in both the xylem and the phloem, and all generally require the addition of an adjuvant to improve leaf coverage and absorption (usually a crop oil concentrate). These herbicides are more effective when applied to unstressed, rapidly growing grasses. Death of the grass is slow, requiring a week or more for complete kill. Symptoms include rapid cessation of shoot and root growth, pigment changes (purpling or reddening) at the leaves occurring within 2–4 days, followed by a progressive necrosis beginning at meristematic regions and spreading over the entire plant.

Acetohydroxy Acid Synthase/Acetolactate Synthase Inhibitors (Group B)

The discovery that small synthetic compounds could inhibit acetohydroxy acid synthase (AHAS; EC 2.2.1.6) revolutionized weed management. The first AHAS-inhibiting compounds discovered, the sulfonylureas, were safe and had significantly lower use rates compared to other widely used herbicides (Beyer *et al.*, 1988; Levitt, 1991). Some sulfonylureas control vegetation at rates below 10 g ai ha^{-1}. A nearly simultaneous discovery of a second group of structurally distinct AHAS-inhibiting compounds, the imidazolinones, increased interest in the target site. Currently, there are five structurally distinct chemical classes that inhibit AHAS: the sulfonylureas,

Table 1 Herbicide Resistance Action Committee (HRAC) classification system in comparison to Weed Science Society of America (WSSA) and Australian code systems (presented in Menne and Köcher, 2012)

Site of action	*Chemical family*	*HRAC group*	*WSSA group*	*Australian group*
Inhibition of acetyl-CoA carboxylase (ACCase)	Aryloxphenoxy-propionate, cyclohexanedione, and phenylpyrazoline	A	1	A
Inhibition of acetolactate synthase and acetohydroxy acid synthase	Sulfonylurea, imidazolinone, triazolopyrimidine, pyrimidinyl(thio)benzoate, and sulfonylaminocarbonyl-triazolinone	B	2	B
Inhibition of photosynthesis at PSII	Triazine, triazinone, triazolinone, uracil, pyridazinone, and phenyl-carbamate	C1	5	C
Inhibition of photosynthesis at PSII	Urea and amide	C2	7	C
Inhibition of photosynthesis at PSII	Nitrile, benzothiadiazinone, and phenyl-pyridazine	C3	6	C
Photosystem I-electron diversion	Bipyridylium	D	22	L
Inhibition of protoporphyrinogen oxidase	Diphenylether, phenylpyrazole, *N*-phenylphthalimide, thiadiazole, oxadiazole, triazolinone, oxazolidinedione, pyrimidindione, and other[b]	E	14	G
Inhibition of the phytoene desaturase	Pyridazinone, pyridinecarboxamide, and others[b]	F1	12	F
Inhibition of 4-hydroxyphenyl-pyruvate-dioxygenase	Triketone, isoxazole, pyrazole, and others[b]	F2	27	H
Inhibition of carotenoid biosynthesis (unknown target)	Triazole, diphenylether, and urea (also C2)	F3	11	Q
Inhibition of 1-deoxy-d-xylose 5-phosphate synthase	Isoxazolidinone	F4	13	Q
Inhibition of 5-enolpyruvylshikimate-3-phosphate synthase	Glycine	G	9	M
Inhibition of glutamine synthetase	Phosphinic acid	H	10	N
Inhibition of dihydropteroate synthase	Carbamate	I	18	R
Inhibition of microtubule assembly	Dinitroaniline, phosphoroamidate, pyridine, benzamide, and benzoic acid	K1	13	D
Inhibition of mitosis/microtubule organization	Carbamate	K2	23	E
	Arylaminopropionic acid	K2	25	Z
Inhibition of very long chain fatty acids (inhibition of cell division)	Chloroacetamide, acetamide, oxyacetamide, tetrazolinone, isoxazoline[a], other[b]	K3	15	K
Inhibition of cell wall (cellulose) synthesis	Nitrile	L	20	O
	Benzamide	L	21	O
	Triazolocarboxamide	L	28	
	Alkylazine	L	29c	
Uncoupling (membrane disruption)	Dinitrophenol	M	24	
Inhibition of lipid synthesis – not ACCase inhibition	Thiocarbamate and phosphorodithioate	N	8	J
	Benzofuran	N	16	J
	Chloro-carbonic-acid	N		J
Action like indole acetic acid (synthetic auxins)	Phenoxy-carboxylic-acid, benzoic acid, pyridine carboxylic acid, quinoline-carboxylic acid, and other[b]	O	4	I
Inhibition of auxin transport	Phthalamate and semicarbazone	P	19	P
Unknown *Note*: Although the mode of action of herbicides in Group Z is unknown, it is likely that they differ in mode of action between themselves and from other groups.	Pyrazolium	Z	26	
	Organoarsenical	Z	17	Z
	Other[b]	Z	26	

Source: Reproduced from Menne, H., Köcher, H., 2012. HRAC classification of herbicides and resistance development. In: Krämer, W., Schirmer, U., Jeschke, P., Witschel, M. (Eds.), Modern Crop Protection Compound, second ed. Weinheim: Wiley-VCH Verlag GmbH & Co, pp. 5–28.

imidazolinones, triazolopyrimidines, pyrimindinyl (thio) benzoates, and sulfonylaminocarbonyl-triazolinones with more than 50 unique active ingredients. Total global market value is estimated at US$3.0 billion, despite the widespread occurrence of resistance.

AHAS catalyzes the first committed step in the biosynthetic pathway of the branched-chain amino acids and is localized in the chloroplasts. Also referred to as acetolactate synthase (ALS), the multisubunit enzyme begins a series of condensation reactions that result in the formation of leucine,

isoleucine, and valine. The inhibition of AHAS by herbicides is a complex time-dependent process that is not well understood. It also appears that each herbicide interacts in a subtle and unique way with AHAS. Binding is a slow-tight reaction, and has been described as uncompetitive or noncompetitive, depending on the individual active ingredient. Several reviews of both AHAS (Umbarger, 1978; Chipman *et al.*, 1998; Duggleby and Pang, 2000; Duggleby *et al.*, 2004; McCourt and Duggleby, 2006; Duggleby *et al.*, 2008 and of AHAS inhibition (Gutteridge and Thompson, 2012) are available.

The sulfonylurea herbicide chlorsulfuron was the first AHAS inhibitor introduced. It was highly selective for broadleaf weeds in wheat. As more analogs were discovered, however, it became apparent sulfonylurea herbicides were not only highly selective but would also control both grass and broadleaf weeds. Similar levels of selectivity were observed in the other AHAS inhibitor chemical classes. Selectivity is often achieved by slight changes in the herbicide molecule base structure. For instance, imazapyr, imazapic, and imazethapyr vary considerably in selectivity (least to greatest, respectively). The addition of a methyl group to imazapyr (largely nonselective) yields imazapic (selective in peanut) whereas the addition of an ethyl group yields imazethapyr (selective in a broad range of legume crops). Behavior in plants and soil by AHAS-inhibiting herbicides is as variable as the compounds themselves. Selectivity is usually achieved by differential metabolism. Soil breakdown is usually through microbial degradation or chemical hydrolysis; however, the combination of chemical properties and activity at very low concentrations can combine to cause very long plant back restrictions that number in years.

Photosystem Inhibitors (Groups C and D)

Shortly after World War II, the ureas became the first major chemical family of the photosystem II inhibitors to be discovered and developed. However, it was not until 1952 that a series of patents were granted to E. I. du Pont de Nemours & Company. As a result of the success of the patent series, DuPont developed and released diuron, fenuron, monuron, and neburon for commercial use. The triazines were discovered in 1952 in Switzerland and initial patent applications were made two years later. Atrazine, simazine, prometryn, and ametryn were the first major compounds to display unique selectivity. The herbicidal activity of diquat and paraquat, the two herbicides that inhibit photosystem I, was first documented and described by Brian *et al.* (1958). The photosystem II and photosystem I inhibitors are among the most important herbicides, and atrazine was the most widely used pesticide globally until it was recently displaced by glyphosate. The Group C herbicides are used in a wide variety of applications, whereas the Group D herbicides are exclusively postemergence nonselective herbicides.

Inhibitors of photosynthesis act by blocking or diverting energy dissipation or transfer within the photosynthetic apparatus, causing accumulations of membrane-disrupting radicals. The processes are well understood, as several members of this herbicide group were used to elucidate the process of photosynthesis. Photosystem II inhibiting herbicides comprise ten chemical families including the amides, benzothiadiazinones, nitriles, phenylcarbamates, phenyl-pyridazines, pyridazinone, triazines, triazinones, uracils, and ureas. Triazines and ureas are the two largest families of the photosystem II inhibitors and are the most widely used. Photosystem I inhibitors consist of one chemical family (the bipyridilliums) and two herbicides (paraquat and diquat). The light-dependent reactions occur in two photosystems known as the PSII and PSI light-harvesting complexes. The two photosystems are pigment–protein complexes spanning the thylakoid membrane within chloroplasts and are associated with the ATP synthase complex (Cobb and Reade, 2010). Light is required directly or indirectly for the activity of herbicides that inhibit photosynthesis.

Photosystem II inhibitors bind to the D1 protein in photosystem II. There are five hydrophobic amino acid helices in the D1 protein that span the thylakoid membrane. What is known as the Q_B binding niche in the D1 protein consists of five hydrophobic amino acid helices spanning the thylakoid membrane (Tietjen *et al.*, 1991; Xiong *et al.*, 1996). The Q_B binding niche is located near the surface of the membrane on the stroma side between the fourth and fifth span of the D1 peptide. When a herbicide occupies the binding pocket, electron flow is blocked, and the resulting singlet chlorophyll energy cannot be transferred to the photosystem II reaction centers. Triplet chlorophyll is formed as the short-lived singlet chlorophyll molecules accumulate, ultimately resulting in an overloading of the carotenoid system and an initiation of lipid peroxidation. Ultimately, membrane destruction is the end result and results in the primary outward symptom of photosystem II inhibitors, necrosis (Hess, 2000).

Group D herbicides, paraquat and diquat (bipyridiniums), divert electrons away from ferredoxin in PSI by competing with ferredoxin to capture electrons (Percival and Baker, 1991). Both are considered contact-type herbicides and are applied to leaves. Phytotoxicity is not only the result of nicotinamide adenine dinucleotide phosphate and ATP depletion, but also through the generation of free hydroxyl radicals from superoxide and hydrogen peroxide accumulation. After capturing electrons, both chemicals form unstable bipyridyl radical cations (Percival and Baker, 1991). The herbicide radical can react with oxygen to form superoxide radicals (O_2^-). The radical is then dissipated through the activity of superoxide dismutase to form hydrogen peroxide (H_2O_2) and α-tocopherol (Halliwell, 1991; Hess, 2000). Hydrogen peroxide is catalyzed or routed through the ascorbate-glutathione cycle to form oxygen and water. However, excessive production of superoxide and hydrogen peroxide form when the herbicides are present both processes are not able to dissipate the resulting accumulation of superoxide and hydrogen peroxide. Subsequently, these two radicals react with each other to create hydroxyl radicals ($OH^{\bullet}$) catalyzed by iron or copper. Hydroxyl radicals initiate lipid peroxidation causing cell membrane destruction as described previously (Hess, 2000). Interestingly, the herbicide, once it has transferred energy from ferredoxin, is available to repeat the process.

Interestingly, the symptoms of chlorosis and necrosis associated with these herbicides do not result primarily by the inhibition of target sites in Photosystem II and Photosystem I. Rather, membrane destruction is caused by lipid peroxidation

of polyunsaturated fatty acids as a consequence of radical formation resulting from photosystem perturbation (Hess, 2000). Thus, photosystem inhibitors differ in their site and mode of action: Photosystem II, Photosystem I, PROTOX, and carotenoid-synthesis inhibitors cause necrosis of plant tissues due to destruction of membrane integrity via lipid peroxidation (Hess, 2000). The process is facilitated by the production of free oxygen radicals and their effects on polyunsaturated fatty acids such as linoleic (18:2) and linolenic acid (18:3). As Hess (2000) described in a thorough review, there are three steps: initiation, propagation, and termination. Initiation begins when radicals such as singlet oxygen (as generated by Photosystem I inhibitors), a hydroxyl radical (as generated by Photosystem II inhibitors), or triplet chlorophyll react with polyunsaturated fatty acids, a component of plant membranes. In the initiation step oxygen interacts with the lipid radical that generates a peroxidized lipid radical, which then reacts with other fatty acid molecules. The process propagates unstable lipid peroxides within the membrane in the second step. In the termination step, lipid peroxide is degraded to short-chain hydrocarbon gases that ultimately lead to damage of plant membranes (Hess, 2000; Halliwell, 1991).

Protoporphyrinogen Oxidase Inhibitors (Group E)

Herbicides possessing protoporphyrinogen oxidase (PPO) (EC 1.3.3.4) inhibiting properties are diverse with over nine structural classifications. All PPO herbicides are classified together as group E by HRAC or group 14 by the Weed Science Society of America (WSSA). Discovery of PPO herbicides began in 1963 with the patent of the diphenylether nitrofen (Wilson and McRae, 1963). From that release, the agrochemical industry launched extensive research efforts to exploit the mode of action as PPO activity exhibited numerous possibilities for compound development. The potential was diminished as many of the highly biologically active compounds lacked clear crop selectivity (Theodoridis *et al.*, 2012). For this reason, PPOs can be used as a nonselective burndown application. Crop-selective compounds have been developed such as fomesafen, the postemergence soybean-selective compound (Cartwright and Collins, 1981) and preemergence soybean compound sulfentrazone (Theodoridis *et al.*, 2012). The latest registry of a PPO herbicide was made in 2009 with saflufenacil and is labeled for uses as a contact burndown herbicide and for preemergence broadleaf weed control in several row crops (Grossmann *et al.*, 2010). Saflufenacil was introduced in part to manage glyphosate-resistant weeds. PPO inhibitors are used primarily as preemergence and some postemergence applications, and their use has increased recently.

Protoporphyrin IX (PPIX), a tetrapyrrole, is the main structural component of both heme, the red-colored cofactor of hemoglobin, and chlorophyll, the green pigment of plants. Heme proteins have a Fe cofactor positioned near the center of the tetrapyrrole ring that serves as a receptor for gaseous XO molecules (X═C, N, O) (Spiro *et al.*, 2013). The PPIX component of chlorophyll found in plants has an Mg cofactor at the center of the tetrapyrrole ring. The chlorophyll structure acts as a light receptor, absorbing energy that is then transferred by resonance to a specific set of chlorophyll molecules (P680 and P700) at the reaction centers of photosystem II and I. Light energy and transfer causes charge separation, redox reaction and donation of an electron that can move through the electron-transport chain leading to the reduction of NADP and a proton gradient in the thylakoid lumen to generate ATP (Raven *et al.*, 2005). The last step in PPIX synthesis is the oxidation of protoporphyrinogen IX by the enzyme protoporphyrinogen IX oxidase (PPO, EC 1.3.3.4), which utilizes molecular oxygen (Matringe and Scalla, 1988; Matringe *et al.*, 1989a,b). The enzymatic step is conserved for both heme and chlorophyll biosynthesis. Inhibition of PPO by herbicides causes the accumulation of the reaction product (PPIX) but not the substrate protoporphyrinogen IX. Excess PPIX undergoes nonenzymatic oxidation in the presence of light and oxygen, which in turn produces large amounts of single oxygen and hydrogen peroxide (H_2O_2) within the cell (Witkowski and Halling, 1988). Reactive oxygen species cause breakdown of membranes through lipid peroxidation of unsaturated fatty acid bonds. Loss of membrane integrity allows for cellular leakage leading to necrosis and death of leaves (Becerril and Duke, 1989). Symptoms of PPO herbicides include a wetting appearance on the leaves followed by yellowing and necrosis. Because of their fast activity, PPO herbicides are designated as contact herbicides and have little to no translocation. Herbicides are applied both foliarly and to the soil as preemergent applications to control sprouting weeds.

Carotenoid Biosynthesis Inhibition (Group F1, F3, and F4)

Carotenoids are essential secondary metabolites initially derived from 5-carbon isoprene units. There are two known pathways in isoprene biosynthesis, the cytosolic mevalonate (MVA) pathway and the plastidial nonmevalonate. A 20-carbon (4 isoprene) geranylgeranyl diphosphate (GGPP) molecule is the building block of carotenoids and many other isoprene-derived metabolites (diterpenes). Joining of two GGPPs forms the precursor molecule to the first committed step in carotenoid production, phytoene, a tetraterpene (Hirschberg, 2001). Subsequent desaturation of phytoene to z-carotene by the enzyme phytoene desaturase (PDS, EC 1.3.99.30) is the target for herbicides grouped by the HRAC in F_1 or WSSA in group 12 (**Table 1**). PDS-targeting herbicides are characterized as pigment synthesis inhibiting or bleaching herbicides. Symptoms are similar to HPPD-targeting herbicides; indeed, PDS and HPPD inhibitors both disrupt carotenoid biosynthesis albeit at different enzymatic steps, PDS being several steps downstream of HPPD. Carotenoid pigments play an important role in photosynthesis as light-harvesting accessory pigments within the light-harvesting complex (Ritz *et al.*, 2000) with a dual function as electron acceptors in photosynthetic electron transfer (Pillai *et al.*, 2013). Carotenoids, particularly carotenes, protect chloroplasts from photo-damaging effects of high-energy oxidative triplet chlorophyll and singlet oxygen by removing excess light or scavenging high-energy species before they can oxidize lipids, proteins, or deoxyribonucleic acid (DNA) (Di Mascio *et al.*, 1990). For further description of carotenoid synthesis and inhibition, refer the Section 4-Hydroxyphenylpyruvate

Dioxygenase Inhibitors (Group F2). Inhibitors of carotenoid biosynthesis are increasingly important herbicides and are widely used in major row crops in premergence and postemergence applications.

Commercial herbicides in group F_1 include seven major active compounds: diflufenican, fluorochloridone, fluridone, flurtamone, norflurazon, picolinafen, beflubutamid. All commercial products, with the exception of picolinafen and fluridone, are applied as pre or early postemergence for broadleaf weed control. Picolinafen can be applied in postemergence applications in cereals, usually in combination with other cereal herbicides. Fluridone is mainly used as an aquatic herbicide to control submerged and emerged aquatic plants but also has selectivity to cotton. Diflufenican and beflubutamid are exclusively applied in cereals whereas fluorochloridone, flurtamone and norflurazon have uses in other crops such as peanuts, cotton, and sunflower.

Although PDS and HPPD herbicides are the main target sites that inhibit carotenoid synthesis, there are other noteworthy herbicides that share bleaching symptoms but have different and in some cases unknown targets. A plant metabolized product of the herbicide clomazone, 5-ketoclomazone, inhibits an early step of the nonmevalonate plastidial isoprene biosynthesis pathway (Ferhatoglu and Barrett, 2006). The compound 5-ketoclomazone inhibits the enzymatic step that joins pyruvate and glyceraldehyde 3-phosphate to make 1-deoxy-D-xylulose 5-phosphate (DOXP, EC 2.2.1.7) hence the designation as a DOXP synthase inhibitor. Clomazone stands alone as group F_4 or 13 by HRAC and WSSA designations, respectively. Clomazone is a broad-spectrum herbicide labeled for use mainly as a preemergent or early post soil-applied herbicide in several vegetable crops and some row crops (Ferhatoglu and Barrett, 2006).

The cyclization of lycopene, a precursor to carotene that gives tomatoes their red color, is another site of action of carotenoid inhibitors. The substituted diethylamine herbicides *N*,*N*-diethyl-*N*-[2-(4-chloro-phenylthio)ethyl]amine) and *N*,*N*-diethyl-*N*-[2-(4-methylphenoxy)ethyl]amine are noncompetitive inhibitors of lycopene cyclase (Schnurr *et al.*, 1998) although their utility as commercial herbicides has yet to be determined. The commercially applied herbicide amitrole, an amino-substituted triazole, causes the accumulation of lycopene that does not appear to directly inhibit lycopene cyclase but rather, an earlier as yet undetermined step in carotenoid biosynthesis (Agnolucci *et al.*, 1996; Fedtke and Duke, 2005; Schnurr *et al.*, 1998). Amitrole is classified with fluometuron and the diphenylether, aclonifen, as unknown target sites in the HRAC F_3 group.

4-Hydroxyphenylpyruvate Dioxygenase Inhibitors (Group F2)

The discovery of herbicides that inhibit the enzyme HPPD (EC 1.13.11.27) began in 1977 with an observation made by a research biologist Reed Gray while working at the Western Regional Utilization Center in California. He noticed that few weeds grew beneath the bottle brush [*Callistemon citrinus* (Curtis) Skeels] plants in his backyard (Gray *et al.*, 1980). After extraction and fractionation of soil samples collected from under the plants, the natural product leptospermone was isolated as the active compound. Leptospermone had been previously discovered in the volatile oils of Australian myrtaceous plants, but biological activity was not characterized with the original discovery (Hellyer, 1968). Pure leptospermone has unique herbicidal bleaching activity but only at high rates ($\sim 9\ kg\ ha^{-1}$) (Gray *et al.*, 1980).

HPPD inhibitors compete with the substrate hydroxyphenylpyruvate, the first step of tyrosine degradation by inhibiting the dioxygenation step (Moran, 2005). When HPPD is inhibited, homogentisate (HG) cannot be formed. HG is a key biosynthetic precursor of plastoquinones (PQ) and plant tocopherols (vitamin E) (Eckardt, 2003; Schultz *et al.*, 1985). Plastoquinones are essential electron acceptors necessary for carotenoid biosynthesis with dual function as electron carriers of photosynthesis. The associated unsaturated prenyl chains of carotenoid molecules also act as electron quenchers to modulate the degradative effects of triplet chlorophyll, a high-energy form of chlorophyll produced naturally during photosynthesis (Pallett *et al.*, 1998). Triplet chlorophyll can further pass this imbalance of energy to oxygen to create unstable singlet oxygen species. Without the quenching effects of carotenoids, plastoquinones and tochopherols chlorophyll itself is decomposed by singlet oxygen (Di Mascio *et al.*, 1990). Excess singlet oxygen can further cause degradation of membrane lipids, protein, and DNA. Lack of PQ and tocopherol coupled with downstream carotenoid absence causes the aforementioned bleaching symptom of treated plants. Although plants may grow for some time after herbicide exposure, deficiency of photosynthates coupled with accumulation of reactive oxygen species eventually overcomes further growth capabilities.

The structure of HPPD inhibitors stem from the original triketone design and are generally formed around a dicarbonyl ketone linkage of cyclic substructures, including isoxazoles and pyrazoles with multiple variations. The herbicide structures appear to bind the iron cofactor at the HPPD active site by mimicking the alpha-keto acid moiety of the natural substrate, hydroxyphenylpyruvate (He and Moran, 2009; Moran, 2005) as confirmed by homology modeling (Kakidani and Hirai, 2003) and herbicide-bound protein crystal structure determination (Brownlee *et al.*, 2004; Yang *et al.*, 2004).

HPPD herbicides have been selected for release based on crop tolerance, particularly to monocot species. Corn is the main selective crop with tolerance to mesotrione (Mitchell *et al.*, 2001), sulcotrione (Beaudegnies *et al.*, 2009), tembotrione (Santel, 2009), topramezone (Grossmann and Ehrhardt, 2007), and isoxaflutole (Pallett *et al.*, 2001). Pyrazolynate (Kubo *et al.*, 2012) and pyrazoxyfen (Copping and Hewitt, 1998) are labeled for use in rice whereas pyrasulfotole is used in small grains like wheat (Reddy, 2012) and sorghum (Fromme *et al.*, 2012). Use of bicyclopyrone is limited to sugarcane (Michel *et al.*, 2010).

5-Enolpyruvylshikimate-3-Phosphate Synthase Inhibitors (Group G)

Glyphosate, the only inhibitor of 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS; EC 2.5.1.19), was first patented by

Stauffer Chemical Company as an industrial cleaner (American Chemical Society, 1997). Monsanto Chemical Company ultimately patented glyphosate as a nonselective herbicide in 1974. Initially, use of glyphosate was low primarily because it was nonselective and expensive. However, with the advent of transgenic glyphosate-resistant crops and the expiration of patents, glyphosate has become the most widely used herbicide in the world. In the United States, glyphosate has been the most commonly used pesticide since 2001, with >81.6 million kg used in 2007 (Grube *et al.*, 2011).

EPSPS is the penultimate enzyme in the aromatic amino acid pathway that ultimately produces tyrosine, tryptophan, and phenylalanine, and is fortuitously absent from mammals (Haslam, 1993). Inhibition of EPSPS depletes these important amino acids from treated plants; in turn, functional proteins cannot be synthesized. Under normal application conditions plant death usually results from depletion of important secondary plant metabolites, particularly those involved with disease resistance. The enzyme EPSPS is localized in the chloroplasts and converts shikimate-3-phosphate into enolpyruvylshikimate-3-phosphate (Amrhein *et al.*, 1980). The introduction of glyphosate to a plant system results in accumulation of shikimate as shikimate-3-phosphate, which is unstable. EPSPS is a monomeric enzyme composed of two domains joined by protein strands. When shikimate-3-phosphate binds to EPSPS, the two domains tighten together to trap the substrate in the active site (Schönbrunn *et al.*, 2001). Glyphosate then permanently occupies the binding site of the second substrate of EPSPS, phosphoenol pyruvate.

Glyphosate, as a zwitterion, is usually formulated as a salt. Three salts have been utilized: isopropylamine, trimesium, and potassium salts. Various uses exist for glyphosate and are usually built around achieving selectivity by placement, timing, or genetic modification. That topic is covered in another part of this Encyclopedia.

Glutamine Synthetase Inhibitors (Group H)

Glufosinate-ammonium is a nonselective, postemergence herbicide introduced in 1981 for total vegetation control. Glutamine synthetase (GS; EC 6.3.1.2) is the target enzyme for glufosinate-ammonium. GS is an important enzyme in nitrogen metabolism responsible for assimilation of ammonia. Ammonia is present in both the cytoplasm and the chloroplast and is produced by nitrate reductase or by photorespiration and deamination reactions,. The enzyme is responsible for the synthesis of the amino acid L-glutamine from L-glutamate, utilizing ATP and ammonia. Glufosinate-ammonium is a nonselective herbicide used in transgenic glufosinate-ammonium resistant crops and in vegetation management applications.

Glufosinate-ammonium is a structural analog of glutamic acid and inhibits GS at its active site; it is competitive with the substrate glutamate for the GS enzyme. Glufosinate appears to form an enzyme-glufosinate-phosphate complex that result in an irreversible inhibition of the enzyme. Symptomology appears rapidly, usually within 5 days. Although the accumulation of ammonia as a result of inhibition of GS by glufosinate is well documented, phytotoxicity can be remediated by the addition of glutamine despite increased accumulation of ammonia (Seelye *et al.*, 1995). Instead of ammonia accumulation causing the observed herbicidal activity, there is evidence that the loss of glutamate, an amino donor for the glycolate pathway, leads to the breakdown of the transamination reaction of glyoxylate to glycine in the photorespiration cycle. The resulting accumulation of glyoxylate inhibits ribulose-1,5 bisphosphate carboxylase/oxygenase, which in turn leads to an inhibition of the light reaction in photosynthesis (Hess, 2000).

Microtubule Assembly Inhibitors (Group K)

Herbicidal microtubule assembly inhibitors (MAI) are most effective when applied to the soil before weed seed germination to control annual grasses and small-seeded broadleaf weeds. Initially, these herbicides, specifically the dinitroanilines, were used as dyes due to their yellow color imparted by the two nitro groups on the phenyl ring. Classified by chemical structure they can be grouped into five families: the dinitroanilines, phosphoroamidates, pyridines, benzamides, and benzoic acids. The microtubule assembly inhibitors are typically used preemergence in an incredible diversity of crops and are among the most widely used family of herbicides.

Microtubles are hollow polymers made up of stacked proteins consisting of alpha and beta tubulin dimers. These dynamic structures form an intracellular network as part of the cytoskeleton that gives both stability and communication pathways within the cell. Microtubules are an integral component of cellular division ensuring proper dissemination of chromosomes to new cells and assisting in plant cytokinesis. MAIs act by inhibiting the ability of microtubules to perform their normal function, mainly during cellular division. MAI compounds are not readily translocated but are absorbed by meristmatic regions at the tips of roots or, to a lesser extent, apical meristems during seed germination. The major symptom of affected plants is root clubbing as a result of isodiametric cell expansion from a lack of cortical microtublues (Lickfeldt *et al.*, 2012). Inability to form root structures deprives the seedling from acquiring water and nutrients, effectively starving and killing the plant before it can establish.

The molecular sites of action of the MAI structural classes are different but all have the same cell-cycle inhibitory effect. The dinitroaniline herbicides bind specifically to the alpha subunit of the tubulin dimer in higher plants, preventing proper polymerization as demonstrated by *in vitro* experiments (Morejohn *et al.*, 1987) and by analysis of weed-resistance mechanisms (Anthony *et al.*, 1999; Hashim *et al.*, 2012). The phosphoroamidates have the same alpha-tubulin inhibitory effects based *in vitro* studies (Morejohn *et al.*, 1987), three-dimensional electrostatic similarities to dinitroanilines (Ellis *et al.*, 1994) and competitive binding to alpha-tubulin between oryzalin and amiprophos-methyl (Murthy *et al.*, 1994). The pyridine and benzamide herbicides do not bind to microtubules assemblies but rather are proposed to inhibit an unknown microtubule-associated protein (Lickfeldt *et al.*, 2012). Disruption of the microtubule-associated proteins affects spindle fibers during prometaphase, causing a shortening of kinetochore microtubules and an inability to properly

segregate chromosomes (Vaughan and Vaughn, 1987). The site of action for the benzoic acid microtubule disruptor chlorthal-dimethyl is yet to be discovered.

Cellulose Biosynthesis Inhibitors (Group L)

Cellulose biosynthesis inhibitors are a group of chemically unrelated compounds that inhibit the incorporation of glucose into crystalline cellulose as demonstrated by radiolabelled ^{14}C-glucose experiments (Dietrich and Laber, 2012). Compounds known to inhibit cellulose biosynthesis include benzonitriles, benzamides, isoxaben, trizolocarboxamides, alkylazines, thiatriazines, and *N*-aryl lactams. Of the several compounds known to inhibit cellulose biosynthesis, only a few have been commercialized, namely, dichlobenil, isoxaben, and indaziflam. All three have similar use profiles – they are applied preemergence and control weeds in the seedling stage, just after germination. All three are primarily used in the tree-fruit, turf, and ornamental markets, as there is no observable effect on established plants. The similarities end there, though, as the discovery of the individual active ingredients occurred over the span of 40 years, and each sparked site of action research ended inconclusively. Cellulose biosynthesis inhibitors are typically applied preemergence and are mostly used in noncropland and perennial crops such as orchards.

Cellulose biosynthesis is too complex to review here. There has been significant progress in our understanding of cellulose biosynthesis in recent years, much of it gleaned from identification of mutants with cellulose deficiencies in *Arabidopsis thaliana* (Guerriero *et al.*, 2010; Taylor, 2008). However, the application of that knowledge to the identification of the mechanism of action of cellulose biosynthesis inhibitors has not resulted in a definitive identification of a molecular target site. There are several candidates targets including proteins associated with the cellulose synthase complex.

Inhibition of Fatty Acid (N) and Very Long Chain Fatty Acid Biosynthesis (K_3)

According to the current HRAC classification, there are two main groups of herbicides that inhibit lipid metabolism on targets other than ACCase, group N and group K_3. Herbicides in group N have four main structural classes, including the benzofurans, chlorocarboxylic acids, phosphorodithioate and thiocarbamates. In group K_3, delineated as inhibitors of very long chain fatty acid (VLCFA), there are five main structural classes: the acetamides, chloroacetamides, oxyacetamides, tetrazolinones and other nonclassified structures. The K_3 herbicides are described as growth/cell-division inhibitors whereas group N are specified as inhibiting cellular metabolism. Common to compounds in both groups is their ability to inhibit long chain fatty acid metabolism effectively hindering growth in the root or shoot of susceptible species. Chemistries from this mode of action have been in commercial use for more than 60 years (Hamm, 1974) and continue to be robust with limited resistance reported (Heap, 2013).

VLCFAs have a long aliphatic carbon chain of >18 carbon atoms that are derived from stearic acid (C18:0). The extension of saturated carbon atoms to the C18 chain is achieved by a microsomal elongation system located in the endoplasmic reticulum and involves fatty acid elongase or 3-ketoacyl-CoA synthase (KCS) enzymes (Blacklock and Jaworski, 2006; Ghanevati and Jaworski, 2002; Joubès *et al.*, 2008; Todd *et al.*, 1999; Trenkamp *et al.*, 2004). VLCFAs serve several biological functions within the plant cell, including integral components or precursors to suberin, cutin and waxes, all important in leaf cuticle formation (Post-Beittenmiller, 1996); in seed storage triacylglycerols; in periderm and endodermis components; in glycosylphosphatidyl-inositol anchors in plasma membrane proteins; in sphingolipid components of various membranes; and in developmental patterning of plant organs (Bach and Faure, 2010; Nobusawa *et al.*, 2013). VLFCAs are synthesized by a multienzyme acyl-CoA elongase systems bound to the cell membrane that catalyzes a string of reactions similar to fatty acid synthase (Fehling and Mukherjee, 1991). Although these compounds have been grouped into mode of action categories based on symptomology and biochemical and physiological evidences, the identity of specific molecular sites of action has remained elusive but with some progress made in recent years. Molecular-genetic studies utilizing loss-of-function mutants, expression profiling and heterologous expression of candidate genes in yeast have identified the enzyme of the first step in VLFCA biosynthesis, KCS, to be a major target of K_3 herbicides (Trenkamp *et al.*, 2004). Interestingly, the N class herbicides did not have the same inhibitory effect in yeast even though VLCFA inhibition had previously been shown (Abulnaja and Harwood, 1991; Abulnaja *et al.*, 1992) and they phenocopy the VLCFA elongase (VLCFAE) mutant *fiddlehead* (Pruitt *et al.*, 2000; Yephremov *et al.*, 1999). Lack of activity in yeast is potentially due to the inability of yeast systems to make the bioactive form of the compounds, or the low bioavailability of the compounds in yeast cells (Trenkamp *et al.*, 2004).

In general, K_3 and N herbicides are applied preemergence or preplant-incorporated to soil. Major weed targets are annual grass species and some small-seeded broadleafs such as lambsquarters and pigweed. Herbicide is absorbed into the meristematic regions of germinating weed seed with little to no translocation following absorption. Arrest of cellular division in the meristems leads to plant death. The chloroacetamides including metolachlor, acetochlor, flufenacet, dimethenamid and others are among the most widely used herbicides due to their exceptional weed control, long residual activity in soil, and crop selectivity. Chloroacetamide herbicides are used in corn, sorghum, soybean, dry beans, peanuts, peas, cotton, and vegetable crops. The latest compound registered in the K_3 group was pyroxasulfone (2013), intended to be as a selective herbicide in corn, soybean, and wheat. The Group N herbicides, the thiocarbamates, including S-ethyl dipropylcarbamothioate, pebulate, butylate, vernolate, and others are used in much the same way as chloroacetamides; however, soil incorporation is important as many are volatile.

Auxin Mimics (Group O)

Otherwise known as growth regulators, auxin-mimic herbicides act as synthetic analogs similar to the plant-synthesized hormone indole-3-acetic acid (IAA). Auxin-mimic herbicides

have a chemical structure characterized by a planar aryl group with attached carboxyl functionality. Molecules can be divided into four main structural classes: the phenoxy-carboxylic acids, benzoic acids, pyridine/pyrimidine carboxylic acids, and quinoline-carboxylic acids. These herbicides are recognized for their low use rates and relative selectivity to monocot species as opposed to broadleaf susceptibility. Application is usually foliar with subsequent systemic translocation, mainly to meristematic regions. The first auxin-mimic, 2,4-D was registered in the United States in 1948 as a result of post WWII research (Cobb and Reade, 2010). Since the registration of 2,4-D, each decade has seen the release of a growth regulator herbicide. Although widely used, weed resistance has been less severe than that observed in 'newer' herbicide modes of action with 30 documented resistant species (Heap, 2013) most of which have limited distribution (Wright *et al.*, 2011). Owing to the robust nature of this herbicide class and the increase in herbicide-resistant weed species, 2,4-D-resistant transgenic crops have been developed that utilize a bacterial aryloxyalkanoate dioxygenase transgene to metabolically breakdown 2,4-D (Wright *et al.*, 2010).

Although auxin mimics are one of the oldest and most widely used herbicide types, the specific molecular site or sites of action have eluded researchers until recently. The past decade has shed light on molecular targets to auxin herbicide perception and response. The auxin-signaling pathway begins with IAA or an auxin-mimic binding to one of the receptors. The first characterized auxin-sensing protein described in *Arabidopsis* is the TRANSPORT INHIBITOR RESPONSE 1 (TIR1) protein; however, five other auxin-sensing proteins called AUXIN SIGNALING F-BOX (AFB) proteins have also been discovered in *Arabidopsis* and are being characterized (Dharmasiri *et al.*, 2005; Walsh *et al.*, 2006). The auxin receptors are F-box proteins and, in conjunction with SKP-1 and CUL-1 proteins, form a plant E3-Ubiquitin ligase complex. On perception by TIR1 or an AFB, auxin-response-transcriptional repressors AUX/IAA are targeted for ubiquitination and degradation allowing an auxin-response-factor protein, a transcriptional activator, to elicit downstream auxin-responsive gene transcription. Endogenous IAA acts as a plant hormone controlling physiological and morphological plant characteristics such as tropic responses, apical dominance, phyllotaxy, and embryogenesis (Muday, 2001; Jenik and Barton, 2005; Leyser, 2005; Reinhardt, 2005). IAA synthesis occurs in the apical meristem and then translocated throughout the plant where it is subject to intensive regulation at synthesis, transport, localization, derivatization, and degradation (Zhao, 2010). Auxin-mimic herbicides are long-lived xenobiotics that

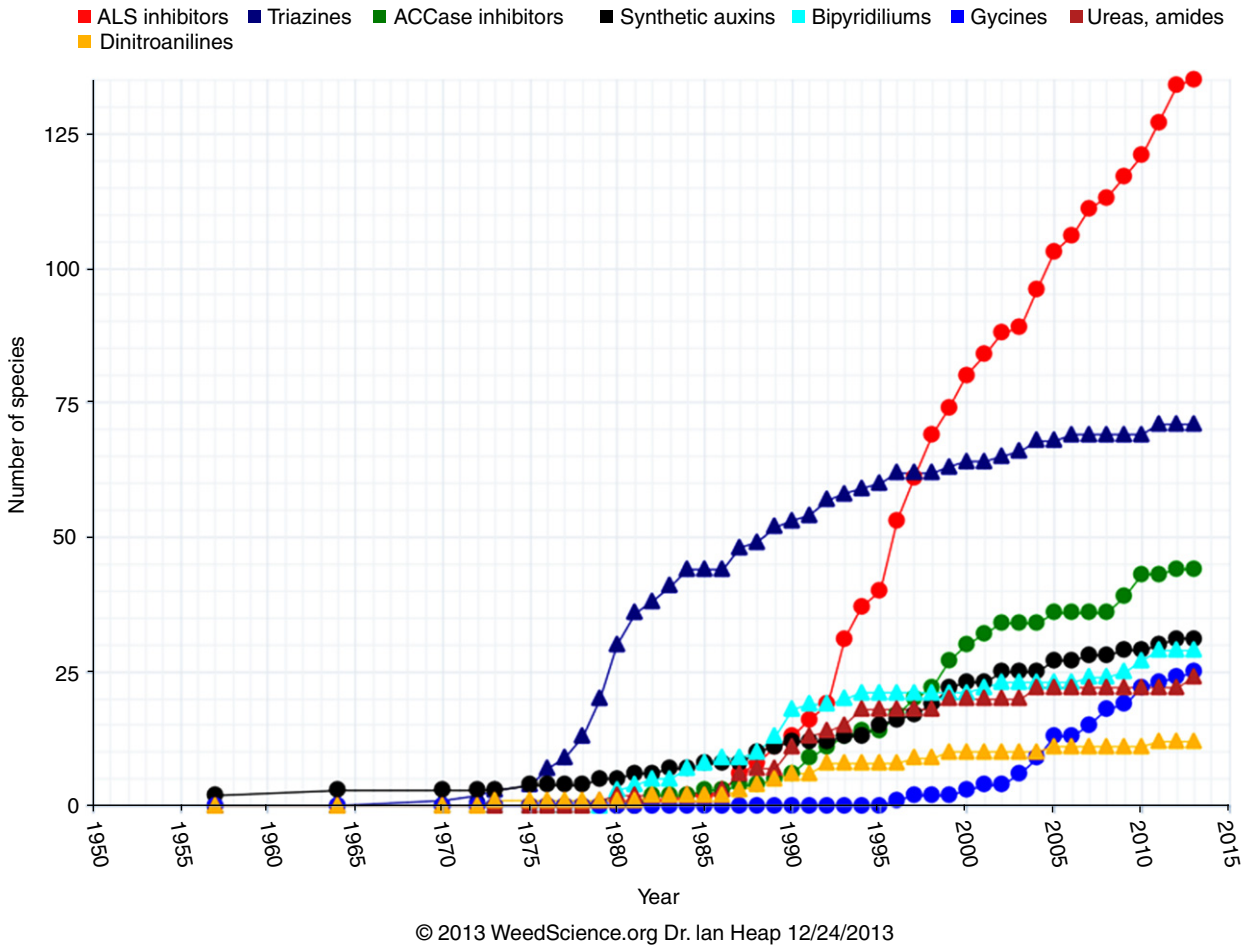

Figure 3 The chronological increase in resitant weeds globally, presented by herbicide mode of action. Reproduced from Heap, I., 2013. International Survey of Herbicide Resistant Weeds. Available at: www.weedscience.org (accessed 15.01.14).

are not subject to endogenous regulation and therefore elicit a prolonged cellular response. At the physiological level, extended auxin signaling by auxin-mimic herbicides causes upregulation in ACC synthase, leading to elevated ethylene levels that, in turn, activates ion channels and $+$H-ATPases, causing abnormal cell elongation and epinasty. Within hours of perception, abscisic acid biosynthesis genes are overexpressed, causing stomatal closure, inhibition of meristematic growth, and senescence. The further production of reactive oxygen species and cyanide leads to membrane degradation, chloroplast damage, and vasculature failure. The summation of metabolic and physiological response causes plant death (Grossmann, 2010).

A main characteristic of auxin mimics is their selectivity, particularly to dicot species. Grass crops do display herbicide injury if applications are made at certain growth stages high rates or applied to environmentally stressed plants. Phylogenetic analysis of the TIR1/AFB receptors from reported plant genomes indicates evolutionary conservation existing before monocot/dicot separation. Indeed, protein comparison between grasses and broadleaf plants reveals little distinction, suggesting that auxin perception is the same (McSteen, 2010). Tolerance in most grass species may be due to differential downstream metabolic and physiological responses (Walsh *et al.*, 2012). It has also been suggested that differences in vasculature anatomy and metabolism may play a role in grass tolerance (Gauvrit and Gaillardon, 1991; McSteen, 2010; Monaco *et al.*, 2002).

Herbicide Resistance in Weeds

Herbicide resistance in weeds, like herbicide fate, constitutes a broad branch of research involving herbicides and is beyond the scope of this article – but it is also the basis for its organization. The development of herbicide resistance in weeds is a major concern because it almost always results in increased costs, particularly in industrialized nations that have embraced the use of herbicides and crops genetically modified to resist them. Herbicide resistance was first documented in the 1970s, although instances of resistance occurred much earlier. There are currently 218 plant species resistant to herbicides globally (**Figure 3**; Heap, 2013), and that number is likely higher as reporting of resistance can be uneven and dependent on active weed science research programs focusing on resistance. Herbicide resistance is first an evolutionary process, and selection for herbicide resistance is dependent on a host of factors involving the genetic basis of the resistance, the biology of the weed species, the attributes of the herbicide, and how it is used (well summarized and reviewed by Powles and Yu, 2010) (**Table 2**). Herbicide resistance, particularly widespread glyphosate resistance in North America, has stimulated a resurgence in herbicide discovery and may well be the impetus for new herbicide modes of action in the future.

Table 2 Factors influencing evolution of herbicide resistance in weed populations

Genetic
Frequency of resistance genes
Number of resistance genes
Dominance of resistance genes
Fitness cost of resistance genes
Biology of weed species
Cross-pollination versus self-pollination
Seed production capacity

Summary

There are many herbicides, and there is significant amount of information available on their use, fate, and mode of action. Herbicides are currently the most readily identifiable tool for management of unwanted vegetation, and an integral part of industrialized weed management systems. In general, knowledge of their mode and mechanism of action is not necessary for their everyday use. However, modern weed managers and scientists are required to be familiar with their nature and properties as such information is needed when the use of herbicides results in unexpected results or when seeking new or novel uses.

Herbicides, like all other tools, can be used and misused. Of all the lessons of the herbicide era, the most important appears to be that herbicides have a limited effective life span, and overuse usually results in a shortened life span. Using herbicides in integrated weed management systems, instead of thinking of them as the primary tool for weed management, is the first step in sustaining the herbicide resource for the future.

Plant Health Management: Pathogen Suppressive Soils

RJ Cook, Washington State University, Pullman, WA, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Antibiosis An antagonistic interaction between two organisms where the outcome favoring one organism over the other is determined by a bioactive chemical to which the unsuccessful organism is sensitive.

Antibiotic A bioactive microbial metabolite that at low concentrations inhibits the growth or metabolic activities of other organisms.

Operational taxonomic units An operational taxonomic unit or taxonomic level of sampling, such as an individual, population, species, genus, or bacterial strain, based on a metagenomic similarity threshold.

Siderophore An iron-chelating compound produced by microorganisms to starve their neighbors of iron and hence have access to other nutrients.

Introduction

Plant diseases caused by soilborne pathogens represent one of the earliest scientific frontiers in plant health management that have seen only minor advances in understanding at the molecular biology and genetics levels in host–pathogen relationships compared with the spectacular advances of the past 25 year for the above-ground pathogens. This is particularly true for the root diseases caused by wide host-range pathogens, such as *Pythium*, *Rhizoctonia*, and *Fusarium* species. Of these three, *Pythium* is the most ubiquitous. Essentially 100% of the plants in a field may have root disease caused by one or more *Pythium* species and more likely one or more *Rhizoctonia* and *Fusarium* species as well. These root diseases can occur so uniformly and completely within a wheat field that they let one to accept the diseased crop as a healthy crop (Cook *et al.*, 1987) or to focus only on whatever disease(s) of the foliage or inflorescence may occur without even considering what may be going on below the ground. Likewise, data on crop losses caused by plant diseases tend to focus on above-ground diseases that are easy to measure using selective fungicides or resistant varieties without considering what the yield of that crop would be if free of root diseases. Nor do data on crop losses account for the environmental effects of root diseases, including nitrogen left unused in the soil, the need for more herbicide because the crop is less competitive with weeds, and less organic matter returned to the soil because of less plant biomass produced (Cook, 1992) – which are all outcomes of unmanaged root diseases. Besides being more difficult to study compared with above-ground diseases, the old adage 'out of sight out of mind' applies to root diseases as well.

Soil fumigation with any one of several gaseous fumigants (methyl bromide, chloropicrin, and metham sodium) is still the best tool to estimate the yield potential of a crop free or nearly free of root diseases. Early work with soil fumigation led to the term 'increased growth response' (IGR), because of the almost universal and often spectacular response of crops to one of these fumigants or to soil solarization (Gamliel and Katan, 2012). However, early and even some contemporary interpretations of the IGR, because it can be so spectacular (commonly 15–20% but also up to 100% greater yield), more often than not discounted root disease control in favor of a response to nitrogen or other nutrients released by the microbial biomass killed by the fumigant. At least four independent studies that went beyond measuring yield increases and also examined the roots came to conclusion that the IGR is due to control of minor root pathogens, especially the ubiquitous *Pythium* spp. (McLaughlin and Melhus, 1943; Bruehl, 1951; Wilhelm, 1965; Cook and Haglund, 1982; Cook *et al.*, 1987). Cook (1992) further showed with wheat at two eastern Washington locations and two fumigants, namely, 1,3-dichloropropane (Telone) and 1,3- dicholorpropane plus 17% chlorpicrin by volume (Telone C17), each at 240 l ha^{-1} injected and roller sealed in the soil, that both caused a flush of ammonium nitrogen in the top 15 cm of soil and that both significantly delayed the conversion of ammonium to nitrate, but only Telone C17 gave the IGR and only Telone C17 eliminated *Pythium* spp. from the soil based on dilution-plate counts on a *Pythium*-selective medium. These results not only confirmed that the flush of nitrogen is real but also experimentally separated the flush of nitrogen from the IGR. A separate study showed that, at harvest, nitrogen was left unused in progressively greater amounts in the wheat rooting zone at incremental depths down to 150 cm in nonfumigated soils but was fully used at all depths down 150 cm in fumigated soils. These results point clearly to the importance of root health to crop growth and use of available nitrogen.

The notion that crop rotation is practiced to maintain the fertility of the soil is erroneous. Other than nitrogen fixed by a legume, crops are net users of nitrogen, phosphorus, and other mineral nutrients. A 3-year wheat/oat/canola rotation or wheat/soybean/sugar beet rotation will deplete the soil of nutrients (that must then be replaced) as completely if not more completely than continuous monoculture wheat, because of less root disease. Yields go down with crop monoculture because the crop is depleted of roots and not because a monoculture crop depletes the soil of nutrients disproportionately more or faster than crops in a rotation. Plants with root disease tend to show symptoms not unlike plants lacking nitrogen, phosphorus, or other nutrient, which, of course, they are lacking, but due to lack of healthy roots and not due to lack of soil fertility.

Options for Management of Soilborne Plant Pathogens

The options available for practical management of soilborne plant pathogens include the following:

- soil treatments, such as fumigation, soil flooding, crop rotation, and soil solarization, to temporarily reduce or eliminate inoculum of soilborne pathogens;
- management of the environment of soilborne pathogens through row spacing, plant density, and planting-date effects;
- reduction of carryover inoculum through burial of infested crop residue and timely elimination of volunteer (self-sown) host plants, also known as green bridge management (Roget *et al.*, 1987; Smiley *et al.*, 1993);
- host plant resistance;
- selective inhibition of pathogens through use of fungicides; and
- biological control, including thorough exploitation of pathogen-suppressive soils.

Of the treatments used to reduce the inoculum load of pathogens in soil, fumigation (Wilhelm and Paulus, 1980), and solarization (Gamliel and Katan, 2012) are not only the most effective but also the most expensive treatments used and therefore are economical only on high-value horticultural crops and nursery plants. Soil solarization is further limited to areas with a hot climate. Soil flooding was once practiced by the United Fruit Company in Central America to control Fusarium wilt of banana (Stover, 1962), which undoubtedly helps to account for the few economically important soilborne pathogens of paddy rice but otherwise is no longer practiced to any extent worldwide. Crop rotations, especially 3-year and longer rotations, allow time for the pathogen(s) of one crop to drop below some economic threshold before planting that same crop in that same field again. However, economic advantages of specializing in one of the two crops have led increasingly to 2-year rotations, double cropping, and continuous crop monocultures worldwide.

Managing the environment of the pathogen is based on the classic host–pathogen–environment triangle, where the host is fully susceptible, the pathogen is both present and virulent, but the environment owing to microclimate effects, for example, dying or warming of the top few centimeters of soil, is less favorable to pathogens, such as *Pythium* and *Rhizoctonia* species. These effects are accomplished with practices such a planting on ridges and spacing the rows wider apart or in pairs rather than uniformly (Cook *et al.*, 2000) but requires the right equipment, timing, and skills. Burial of crop residue by deep plowing can be effective, especially when combined with a 2- or 3-year crop rotation but is also contrary to the need for greater adoption of no-till or direct-seed practices to save soil, water, time, and fuel while improving soil quality and often also providing more habitats for wildlife.

Except for host-specific pathogens, such as those responsible for Fusarium wilts of different crop species, virtually no progress has been made in the development of useful host plant resistance to soilborne plant pathogens. Even for root diseases caused by pathogens with a fairly narrow host range – such as *Gaeumannomyces graminis* var. *tritici*, cause of take-all of wheat and related grasses, and *Fusarium solani* f. sp. *pisi*, cause of root rot of peas – attempts initiated during the past century to find useful variation in resistance/susceptibility within the host species and its wild relatives have been unsuccessful and largely abandoned. Moreover, any evidence of resistance or tolerance in experimental field tests can be so subtle and variable that it requires a fully susceptible check strategically placed at multiple locations throughout the experimental test site so as to always have a check close by for comparative purposes. In addition, distinguishing differences in resistance or susceptibility of plant varieties and lines to a root disease require confirmation, meaning that the plant's roots must be dug from the soil, washed free of soil, and examined, which is inherently tedious work.

There has also been relatively little progress in the development of fungicides for control of soilborne plant pathogens. One exception is the oomycetes, including *Pythium* and *Phytophthora* species. As a research tool, granular metalaxyl applied in-furrow confirmed that *Pythium* root rot of wheat in eastern Washington was so uniform that, without the treated rows for comparison, one would believe that the untreated rows were perfectly healthy wheat (**Figure 1**). In practice, metalaxyl is used only as a seed treatment to protect the germinating seeds and then in combination with a fungicide to inhibit seed and seedling infection by *Rhizoctonia*, thereby avoiding a classic problem of control only of *Pythium* that can lead to more damage from *Rhizoctonia* and vice versa. Unfortunately, today's fungicides applied to seeds protect seeds during germination but do little on nothing to protect roots from infections.

Pathogen-Suppressive Soils Defined

Pathogen-suppressive soils have been defined as "The inhospitality of certain soils to some plant pathogens is such that either the pathogens cannot establish, they establish but fail to produce disease, or they establish and cause disease at first but

Figure 1 Winter wheat direct seeded (no-till) into standing wheat stubble with nitrogen, phosphorus, and sulfur applied below the seed in each seed row at planting, and metalaxyl also applied as a granular in the four indicted seed rows with the seed at planting, for control of Pythium root rot. Note that similar to the response of wheat and other crops to soil fumigation, except for the four treated rows, the check rows would be considered healthy.

diminish with continued monoculture of the crop" (Baker and Cook, 1974). The opposite of soils suppressive to plant pathogens are soils conducive to plant pathogens.

The suppressiveness of soils to pathogens has been further subdivided into 'general suppression' and 'specific suppression' (Weller *et al.*, 2002). General suppression relates usually to the total microbiological activity of the soil in contrast to specific suppression, which relates to the antagonistic activity of a specific group of microorganisms or possibly a single microbial species suppressive to a specific soilborne pathogen, operating in addition to and against a background of general suppression. Another key distinguishing feature is that general suppression is a natural and preexisting characteristic of soil and is not transferrable from field to field, whereas specific suppression develops in response to the presence of the pathogen or disease and is transferable from one soil to another. Although categorizing suppressive soils into these two types is useful for discussion, they should more appropriately be viewed not just as a combination but also as a continuum from general to specific suppression and as the likelihood of general suppression giving rise to specific suppression in response to specific cropping systems or management practices.

The existence of pathogen-suppressive soils has been recognized by growers and plant scientists since early in the twentieth century. Unfortunately, very few studies were carried out in those years to fully document the existence of these soils experimentally, because the priority typically would be to work on diseases that were problematic and not on those that were not problematic or that disappeared more or less spontaneously. Nevertheless, enough of the early day plant pathologists showed enough curiosity to at least document the occurrence of certain pathogen-suppressive soils long before the emergence of the molecular methods used today to characterize and shed light on the novel microbiological properties responsible for biological control of pathogens in these soils.

Today, research aimed at understanding the mechanisms responsible for the suppression of pathogen populations or their ability to cause disease is among the more scientifically interesting and exploitable areas of research on molecular plant–microbe interactions. Moreover, because the basis of soil suppressiveness to pathogens has thus far been shown to be microbiological, and not chemical or physical, pathogen-suppressive soils have never been considered anything other than examples of biological control caused by resident (indigenous) microorganisms. The suppression may be either direct through starvation, parasitic exploitation, or production of an antibiotic inhibitory to the pathogen (Cook and Baker, 1983) or indirect through induced resistance in the host plant to the pathogen (van Loon *et al.*, 1998).

General Suppression

Soilborne plant pathogens spend the great majority of their existence as dormant structures (chlamydospores, oospores, sclerotia, and dead host tissue colonized by the pathogen through parasitism while the host was still alive) waiting for a host root to come to them. Other than the rare exception, such as the production of root-like rhizomorphs by *Armillaria* species, soilborne plant pathogens do not grow through soil seeking a host root. This dormancy, known as 'soil fungistasis,' is universal to all soils (Lockwood, 1964). It is also universally overcome by nutrients, usually the simple sugars and amino acids (also volatiles) that diffuse as exudates from roots as they grow through soil. This is obviously an important survival mechanism for soilborne pathogens, as it assures that they remain dormant and therefore in relative safety until a host is nearby. It can be assumed that the signal(s) that trigger(s) germination or other response of the pathogen also 'tell' the pathogen which way to grow. Not surprisingly, the larger the survival structure or food base, the greater the distance the pathogen can grow to reach a host root, but the distance is still more likely in millimeters and not in centimeters (Wilkinson *et al.*, 1985). Conversely, the more suppressive the soil to that pathogen, the nearer to the root the pathogen must be to infect the root (Wilkinson *et al.*, 1985). Pathogens that survive as relatively small structures (20–50 um in diameter), such as oospores (*Pythium* spp.) and chlamydospores (*Fusarium* spp.), make up for their small size with numbers. Eastern Washington wheat field soils, for example, have an average of approximately 200 propagules of *Pythium* species (oospores and thick-walled sporangia) per gram in the top 15 cm of soil (Cook *et al.*, 1987). At a bulk density of 1.2 g cc^{-1} of soil, this translates to an average of approximately 240 propagules per cm^3 or 1 propagule in per 4 mm^3 of soil. No root as it emerges from a geminating seed and passes through the zone of greatest infestation can avoid coming into direct contact with several of these propagules.

General suppression need to be no more than an outcome of the rate at which root exudates or other nutrient sources are consumed by microorganisms in the rhizosphere. Think of the microbiological activity of soil as a fire burning the available carbon and energy sources as they are released from roots, where the greater the intensity of microbiological activity, the faster the rate of burn, the greater the general suppression, and the nearer the pathogen propagule must be to the root to have any chance of receiving sufficient nutrient to trigger germination and reach the root. Soils rich in organic matter because of regular inputs of decomposable biomass are generally more suppressive than soils naturally low in organic matter, such as arid lands or soils depleted of their organic matter because of years of tillage and removal of crop residue. Organic amendments in the form of barnyard manure and composts were among the first treatments shown already during the first half of the twentieth century to control a wide range of soilborne pathogens without understanding the mechanism(s) involved (Reviewed in Baker and Cook, 1974).

Broadbent and Baker (1974a,b; Reviewed in Baker and Cook, 1974) documented an example thought to be 'pathogen establishes but fails to produce disease' in their work with Phytophthora root rot of organically managed avocado trees in a rain forest environment of south Queensland, Australia. An avocado grove established in the early 1940s was still healthy with large high-yielding trees after 40+ years, in spite of growing in soil infested with *Phytophthora cinnamomi* and with 152 cm average rainfall known to favor this pathogen. In contrast, root rot caused by this pathogen was severe in groves of the neighbors of this grower. Suppressiveness was associated with soil organic matter maintained at approximately

12%, close to the natural surrounding rain forest soils before the orchard area was cleared and planted to avocado. This was accomplished by adding copious quantities of biomass as chicken manure, plowed-down corn stalks, and any other source of plant material that might have been available, along with calcium, with pH maintained between 6.0 and 7.0. In contrast, soils had become more acidic and the soil organic matter was mostly depleted by oxidation in neighboring orchards with extensive root rot and where no effort had been made to maintain a soil organic matter content similar to the surrounding undisturbed rain forest soil.

Essentially the healthy orchard was managed organically and the soil was described as a really 'live soil' based on the diversity and size of the microbial biomass. It would seem likely, therefore, that this is an example of general suppression. Although no particular organism or group of organisms could be shown to account for the suppressive effect, nor was the suppressiveness transferable, it was eliminated by waterlogging the soil and overcome by adding excessive quantities of *P. cinnamomi* inoculum. Increasing the inoculum density of the pathogen would effectively increase the number of propagules in direct contact with the root. No further research has been done to explain more fully the basis for the suppressive effect, but presumably the neighbors will have long ago adopted the organic method of managing their avocado orchards.

Soil solarization has also been shown to result in soil suppressive to pathogens, exemplified mainly by failure (or delay) of pathogens to recolonize the treated soil (Kassaby *et al.*, 1985; Greenberger *et al.*, 1987; Freeman *et al.*, 1990). The relatively mild heat, especially at lower depths, similar to pasteurization, is thought to kill inoculum of pathogens more efficiently than inoculum of saprophytes then left to recolonize the treated soil. Soil saprophytes are typically more thermotolerant than the inoculum of fungal and oomycete pathogens (Cook and Baker, 1983). The rapid colonists and likely antagonists of soilborne pathogens identified after soil solarization include *Trichoderma* spp., strains of the *Pseudomonas fluorescens* group, *Bacillus* spp., *Gliocladium*, and *Talaromyces*.

There is an assumed metabolic cost to propagules during their imposed dormancy in natural soil based on the observation that survival is longer if not indefinite in sterile soil but clearly finite in natural soil. A large metabolic cost and hence a shortened life expectancy for the pathogen owing to an intensely active soil microbiota would be an example of general suppression accounting for a failure of the pathogen to survive until the arrival of its host. The half-life of *Fusarium culmorum*, cause of *Fusarium* root and crown rot of wheat, was estimated at 215 days in a Ritzville silt loam with 250 cm annual rainfall and 350 days in a Palouse silt loam with 500 cm annual rainfall (Inglis and Cook, 1986). Both locations are in eastern Washington. Obviously a 1-year break from wheat or barley would not be long enough to control this pathogen by crop rotation at either location without the means to intensify microbial activity of these soils and thereby increase the metabolic cost to propagules during their dormancy. Unlike the tropical soils of south Queensland, the challenge for eastern Washington with its Mediterranean-like climate (most precipitation occurring during the fall and into spring, with dry summers) is that soils are cold and sometimes frozen when moist enough for microbiological activity and dry when warm enough for microbiological activity.

There is a risk when attempting to increase the suppressiveness of soils to pathogens by addition of organic matter if the biomass added is alive, for example, green manure. Soilborne plant pathogens are typically facultative parasites, meaning they can obtain their nourishment from either dead tissue (as a saprophyte) or live tissue (as a parasite). Thus, as long as the green manure remains alive in the soil, which could be 1 or 2 days or longer in moist soil at a favorable temperature, the only serious competition for colonization of the green tissues by a facultative parasite, such as a *Pythium* species, will be other facultative parasites. Trujillo and Hine (1965) showed that a high rate of mortality of papaya seedlings transplanted into soil where live residue of the previous papaya crop had been incorporated was due to buildup of *Pythium aphanidermatum* and *Phytophthora parasitica* on the live residue, thereby using the residue as a food base to attack the young papaya seedling. Before their work, the problem had been ascribed to toxicity of the papaya residue to the young papaya seedlings transplanted into the soil containing the residue.

However, pathogens that depend for survival between host plants on dead tissues of their host colonized through parasitism while the plant was still alive are then vulnerable to displacement within this food base by strict saprophytes, depending on their ability to maintain possession of this food base until a new host arrives (Bruehl, 1975). This vulnerability can explain why *G. graminis* var. *tritici*, cause of the root disease of wheat known as take-all, is controlled by only a 1-year break from wheat in the southeast United States, where soil microorganisms are active essentially year round, but requires a 2-year break or longer from wheat in the Inland Pacific Northwest, where soils typically are too dry for microbiological activity when warm and too cold when wet. Tang Wen-hua (unpublished) established a mutant strain of the take-all pathogen resistant to the fungicide benzimidozole in autoclaved oat grains that was then reduced to smaller particles in a coffee grinder, infiltrated the particles with a solution of benzimidozole, and added them as an inoculum source in soil in pots planted to wheat. The same oat grain particles colonized by the pathogen but infiltrated only with water were used as the control. The severity of take-all where benzimidozole-infiltrated inoculum was used was double of that where inoculum infiltrated only with water was used. The experimental design was based on the hypothesis that limiting colonization of the take-all pathogen's foodbase by competing fungi with a fungicide, such as benzimidozole, would increase the inoculum potential of this pathogen, which obviously is what happened.

Bruehl *et al.* (1969) showed that *Cephalosporium gramineum*, cause of a vascular disease of wheat known as Cephalosporium stripe, maintains possession of its food base (wheat straws colonized through parasitism) by production of a broad-spectrum antibiotic inhibitory to microorganisms that otherwise would colonize the straw and potentially displace *C. gramineum*. Antibiotic-negative mutants failed to survive, whereas wild-type strains survived in straw buried in soil up to two years. In essence, the antibiotic functions like benzimidozole in the experiment described above for protection of the

take-all pathogen from displacement in its food base by soil saprophytes. In this example, the antibiotic produced by *C. gramineum* serves to counter what otherwise would be an example of the pathogen failing to survive.

Rhizoctonia solani AG-8, cause of root rot of wheat, barley canola, peas, and safflower, among other hosts, lives between host crops as a colonist of roots, typically small roots. Hence, this pathogen is vulnerable to displacement relatively quickly, i.e., within a month or less, owing to colonization and decomposition of its food base by competing microorganisms in soil. Root tissues have a much lower carbon to nitrogen (C:N) ratio than stem tissues consisting of cellulose and lignin and therefore are more rapidly decomposed than stem tissues when dead. However, because of its wide host range, breaks between hosts need to be a plant-free fallow for at least a month when soil conditions are favorable for microbiological activity and longer if the fallow period includes winter months with subfreezing temperatures or an extended dry period (Roget *et al.*, 1987; Smiley *et al.*, 1993).

Suppression of pathogens through competition for their food base, potentially even displacing them in their food base, is one of the more common mechanisms of general suppression exemplified by a failure of the pathogen to survive. This form of suppression is among the most exploitable suppressions using crop rotation where enough time is allowed between host crops for displacement of the pathogen in its food base.

Role of Antibiosis in the Survival and Suppression of Soilborne Plant Pathogens

Antibiosis in the broadest sense of the term is an antagonistic interaction between two organisms where the outcome favoring one organism over the other is determined by a bioactive chemical to which the unsuccessful organism is sensitive. Antibiosis is an example of allelopathy usually applied to describe an antagonistic interaction between plants through production of a phytotoxic chemical. Two well-studied mechanisms of antibiosis postulated to be involved in pathogen-suppressive soils are inhibition by production of an antibiotic (Thomashow and Weller, 1995) and iron starvation by production of an iron-binding siderophore (Schroth and Hancock, 1982). Either mechanism of inhibition provides a means by which one organism can more effectively compete for carbon or other nutrient(s) in short supply, especially with its nearest relatives likely to depend on the same nutrients. Production of antibiotics and siderophores, whether in the rhizosphere, within the food base of a pathogen, or in the bulk soil, are site-specific processes. In other words, soil is not awash in these substances, even soils maintained at 12% organic matter content, such as the avocado orchard in south Queensland. For antibiosis to play a role in suppressive soil, the bioactive substance would need to be produced in the niche(s) occupied by the pathogen and the pathogen would need to be sensitive to the antibiotic or siderophore. More recent work shows further that antibiotics produced by bacteria modulate other processes essential to survival and function of the producing bacteria (Raaijmakers and Mazzola, 2012). Overall, the evidence is clear that antibiosis plays a role in the suppressiveness of soils to pathogens, both general and specific suppression.

Strains and species within the *P. fluorescens* group (within the γ subclass of Proteobacteria) have received the greatest attention because of their ability to produce a wide array of antibiotics and siderophores. Two factors led early to a focus on this large taxon of gram-negative bacteria and their roles in disease suppression: they were readily culturable, which opened the way for microbiologists and chemists to purify and work out the biochemistry of antibiotic biosynthesis; and the development of a semiselective medium (Rovira and Sands, 1970) that made it possible before the days of polymerase chain reaction (PCR) and other molecular methods to quantify their populations in soil and the rhizosphere. At least four antibiotics produced by the *Pseudomonas fluorscens* group, namely, pyoluteorin, pyrolnitrin, 2,4-diacetylphloroglucinol (DAPG), and phenazine-1-carboxylic acid, were early targets of research on their roles in disease suppression (Weller *et al.*, 2002). Moreover, the ability of different strains each to produce one or more of these antibiotics was shown to be highly conserved worldwide in subpopulations within the rhizospheres of different crops. Genome sequencings now reveal that the *P. fluorescens* group is even more diverse and heterogeneous than previously realized. A comparative analysis of the genomes of 10 strains of plant-associated *Pseudomonas* strains or species shown through previous studies to provide biological control of plant pathogens revealed that the core genomes (genes present in all 10 strains) made up only approximately half of the genes in any individual strain (Loper *et al.*, 2012). Roughly the other half of the genes in the ten strains consisted of each strain having hundreds of genes unique to that strain and responsible for the biosynthesis of the antibiotic 2-hexyl-5-propyl-alkylresorcinol, siderophores, and other biologically active metabolites not previously known to be produced by those strains.

In what is the first area-wide study of the natural production and accumulation of an antibiotic in a plant rhizosphere, D. Mavrodi *et al.* (2012) determined the populations of indigenous strains of *Pseudomonas* spp. with ability to produce the broad-spectrum antibiotic phenazine-1-carboxylic acid (Phz+ *Pseudomonas* spp.) in the rhizosphere of wheat collected from 61 commercial fields of winter wheat in an area of approximately 22 000 km^2. The area sampled stretches from north central Washington into northeastern Oregon and northern Idaho and is the largest contiguous cropping area in the Western United States. Cells of *Pseudomonas* spp. recovered from the wheat rhizosphere by dilution planting on the semiselective medium were screened by PCR for the *phzF* gene, one of a seven-gene locus shown earlier (Mavrodi *et al.* (1998)) to account for biosynthesis of phenazine-1-carboxylic acid. Liquid chromatography of processed samples representing wheat roots and tightly adhering soil was used to detect and quantify the antibiotic. Phz+ pseudomonads were detected in all fields sampled in populations ranging from log 3.2 to 7.1 g^{-1} fresh weight of root. The antibiotic was also detected, in nanogram amounts per gram fresh weight of roots from 26 of 26 fields selected, with a highly significant and direct relationship between the population of Phz+ pseudomonads and the amount of accumulated antibiotic. Of particular interest, there was a highly significant inverse

correlation between annual precipitation and root colonization by Phz+ pseudomonads, with the highest proportion of plants with roots colonized by Phz+ pseudomonads in areas receiving 350 mm of annual precipitation or less. This part of what is known as the Columbia Basin has been under cultivation for approximately 125 years, mostly in a dryland (rainfed) 2-year winter wheat/fallow rotation (one crop produced with two years of precipitation). Samples collected in the higher rainfall areas farther east toward and along the Idaho/Washington border (the Palouse) cropped annually in cereal-intensive or cereal/pulse rotations had the lowest frequency of Phz+ pseudomonads.

O. Mavrodi (2012) quantified the comparative frequencies and population densities of both Phz+ pseudomonads and strains of the *P. fluorescens* group with ability to produce the antibiotic DAPG (Phl+) in the semiarid region (150–300 mm annual precipitation) of the Columbia Basin for both rainfed and irrigated wheat. The method used to quantify Phl+ strains was similar to that used by D. Mavrodi for Phz+ strains, using PCR to screen cells with *PhlD*, one of a six-gene cluster shown to account for biosynthesis of this antibiotic (Bangera and Thomashow, 1999). Only Phz+ pseudomonads were detected in the rhizosphere of rainfed wheat. In contrast, of the 10 wheat fields irrigated by center pivot, all were colonized by Phl+ bacteria. From half to 100% of the roots from irrigated fields were colonized by Phl+ bacteria compared with less than half the roots in these fields colonized by Phz+ bacteria. Phz+ pseudomonads were below the detection level in 3 of the 10 irrigated fields.

These remarkable results point clearly to a role of Phz+ and Phl+ production and accumulation in the rhizosphere of wheat as an example of, potentially, a general suppression of what root pathogens provided by indigenous strains of the *P. fluorescens* group. Shifting from historically rainfed to irrigated wheat also shifted the makeup of the two populations from Phz+ dominant to Phl+ dominant. *Rhizoctonia* root rot and *Fusarium* root and crown rots are the dominant diseases in the lower rainfall areas, whereas take-all caused by *G. graminis* var. *tritici*, present at subclinical levels on rainfed wheat in this semiarid region, develops quickly into epidemic proportions once the wheat is irrigated. The widely documented spontaneous decline of take-all with continuous monoculture of wheat under high-rainfall or irrigated conditions and an example of specific suppression (see below) is due to Phl+ pseudomonads achieving threshold populations of log 6–7 g^{-1} fresh weight of wheat roots on essentially 100% of the roots (Weller *et al.*, 2002). *Rhizoctonia* root rot of wheat and barley in both Australia (Roget *et al.*, 1999) and the semiarid Inland Pacific Northwest has been documented to increase in importance with direct seeding but then decline after several more years of the same management (see below). *Rhizoctonia* is highly sensitive to phenazine-1-carboxylic acid that may provide some level of general suppression of this pathogen in the wheat-fallow rotation with mulch tillage but, similar to take-all decline (TAD), exemplify an example of control by induced suppression after several year of continuous wheat and barley sequences with direct seeding.

The role of siderophores in pathogen-suppressive soils received a great deal of attention by researchers in the 1980s (Kloepper *et al.*, 1980a,b; Schroth and Hancock, 1982). These studies also gave rise to the term Plant Growth-Promoting Rhizobacteria, referring to the IGRs when seeds of sugar beets or seed pieces of potatoes, for example, were treated with cell suspensions of siderophore-producing bacteria. Virtually all were members of the *P. fluorescens* group. In one study, soils suppressive to *G. graminis* var. *tritici*, cause of take-all of wheat, and *Fusarium oxysporum* f. sp. *lini*, cause of Fusarium wilt of flax, became conducive to these diseases with the addition of Fe(III)EDTA-, a form of iron highly available to microorganisms (Kloepper *et al.*, 1980a,b). Conversely, when a siderophore-producing pseudomonad or its siderophore psuedobactin were added to the conducive soil, the soil became suppressive to the two pathogens in separate tests. As there has been no clear evidence that siderophores contribute specifically to the suppression of a given pathogen on a given crop to fit with examples of specific suppression, yet are clearly factors in the antagonistic interactions of microorganism and soilborne plant pathogens, siderophore-producing soil and rhizosphere bacteria should be considered part of background (general) suppression.

Reflecting on the lack of genes for host plant resistance to soilborne plant pathogens, Cook *et al.* (1995) hypothesized that the plants may have evolved a different strategy for defense against root pathogens, namely, interactions with antibiotic-producing rhizosphere microorganisms. Stated another way, the widespread and even ubiquitous occurrence of these beneficial bacteria and especially their tendency as in the case of TAD to increase in numbers and activity in response to the disease on monoculture wheat would surely have eliminated or greatly diminished selection pressure on the host for resistant genotypes over the course of the evolution of this plant species and its relatives. Although crops species evolved as polycultures, crop rotation is an artifact of agriculture. Wheat and barley in particular evolved with their close relatives in almost solid stands in the Fertile Crescent, reseeding themselves in the same places and without benefit of tillage over centuries. With the tools now available to detect and quantify populations of antibiotic-producing bacteria over wide areas, as described above for rainfed wheat in Pacific Northwest Columbia Basin, the tools are now available to verify the extent to which this hypothesis is correct.

Specific Suppression

Fusarium Wilt-Suppressive Soils

One of the earliest-reported examples of a pathogen-suppressive soil, althought to result from failure of the pathogen to establish, was soil in Central America tolerant and intolerant to *F. oxysporum* f. sp. *cubense*, causing Fusarium wilt of banana (Reinking and Manns, 1933; Stover, 1962). Soils were classified as short, intermediate, and long life according to the length time required for an orchard to become unproductive because of wilt. Virtually 100% of the banana plants would die from wilt within 3–4 years in short-life soils but remain healthy and productive for 20–30 years in long-life soils. Some long-life soils were only a few yards from short-life soils. Snyder and Walker (1933), working in Wisconsin with the *F. oxysporum* f. sp. *pisi*, cause of Fusarium wilt of peas,

documented what they termed 'wilt-resistant soils,' whereby the pathogen established and spread rapidly in two different loams but failed to establish in Superior red clay, even when this soil was transported to and tested for potential for development of wilt in plots adjacent to the wilt-conducive loams.

Fusarium wilts are caused by different subspecies of *F. oxysporum* known taxonomically as formae speciales or f. sp., usually named after the species name of the host plant – f. sp. *lini* for the wilt pathogen of flax, f. sp. *cubense* for the wilt pathogen of banana, f. sp. *nivem* for the wilt pathogen of watermelon, f. sp. *lycopersici* for the wilt pathogen of tomato, f. sp. *pisi* for the wilt pathogen of peas, etc. Many formae speciales, in turn, are made up of races pathogenic to specific varieties of that plant species. Examples of soils suppressive to Fusarium wilts have been reported for a wide array of formae speciales on their respective host plants (Weller *et al.*, 2002), and soils suppressive to wilt caused by one formae speciales can also be suppressive to wilt caused by other formae speciales (Scher and Baker, 1980). Consistent with the classification of wilt-suppressive soils as examples of specific suppression, the suppressivness is eliminated by moist heat treatment as low as 54 °C (Scher and Baker, 1980) or γ-radiation (Alabouvette *et al.*, 1977) and is transferable by mixing a small amount of suppressive soil into a conducive soil or a suppressive soil rendered conducive by heat or other treatment (Alabouvette, 1986; Scher and Baker, 1980). Moreover, the suppressivness is specific to Fusarium wilts and does not affect *Fusarium* root rots (Weller *et al.*, 2002). In the case of *F. oxysporum* f. sp. *nivem*, suppressiveness was induced following four successive plantings of a moderately resistant variety of watermelon but not by four successive plantings of a fully susceptible variety of watermelon (Larkin *et al.*, 1993).

Most investigations of wilt suppression have identified a role for:

1. nonpathogenic *Fusarium* spp., including nonpathogenic *F. oxysporum* as competitors for carbon in the rhizosphere (Alabouvette, 1986; Larkin and Fravel, 1999);
2. induced resistance in response to certain strains of nonpathogenic *F. oxysporium* (Larkin and Fravel, 1999);
3. siderophore-producing strains of *Pseudomonas* bacteria that starve the pathogen of iron in the rhizosphere or during the infection process (Scher and Baker, 1980); and
4. phenazine (*phzC*+) antibiotic produced by fluorescent *Pseudomonas* spp. acting synergistically with carbon competition from nonpathogenic *F. oxysporum* (Mazurier *et al.*, 2009).

Mazurier *et al.* (2009) compared the frequency of antibiotic-producing fluorescent *Pseudomonas* species in bulk and rhizosphere soils conducive and suppressive, respectively, to Fusarium wilts. The suppressive soil was from the Chateaurenard region of France and shown through extensive earlier studies by Alabouvette (1986) to be highly suppressive to Fusarium wilts of several crops. Fluorescent *Pseudomonas* spp. positive for production of DAPG (PhlD+) were not detected in bulk soil of either the conducive or suppressive soil. In contrast, strains positive for production of phenazine (PhzC+) were detected in bulk-suppressive soil but not bulk-conducive soil. When the populations of these antibiotic-producing bacteria were determined for rhizosphere soil of both flax and tomato, PhzC+ strains were not detected in the conducive soil but were readily detected in the rhizosphere of these two wilt suscepts in suppressive soil. Strains of PhlD+ bacteria were marginally detected in rhizosphere soil of both plants in both conducive and suppressive soils. In tests for biological control, antibiotic-negative (PhlD–) and wild-type strains (PhlD+) were equally suppressive to wilt of flax alone or in combination with nonpathogenic *F. oxysporum*, indicating that the phloroglucinal antibiotic had no role in wilt suppression. In contrast, a mutant strain negative for production of phenazine was also negative for disease suppression when combined with carbon competition from *F. oxysporum*.

Mazurier *et al.* (2009) proposed a model that takes into account all four mechanisms of wilt suppression acting synergistically or sequentially. A greater microbial biomass in the Chateaurenard soil compared with the conducive soil was proposed to provide a naturally more intensely competitive soil environment as a background to the more specific mechanisms of carbon and iron competition and phenazine antibiosis. Their model also takes into account several physical and chemical factors of soil, such as a higher pH in the suppressive than the conducive soil, making iron less available and hence competition for iron more critical.

The fact that Fusarium wilt-suppressive soils have been identified for many different formae speciales of the pathogen and that soils suppressive to wilt caused by one formae speciales are also suppressive to wilt caused by other formae speciales, would suggest a common mechanism of suppression. Induced resistance in response to nonpathogenic *F. oxysporum* could well be that common mechanism enhanced by a background of general suppression includes the other demonstrated mechanisms of suppression – competition for carbon and iron and production of phenazine antibiotic. In one of the clearest examples of induced resistance, Larkin and Fravel (1999) used a split-root system to show that of the three different isolates of nonpathogenic *Fusarium* spp. found earlier to limit the incidence of Fusarium wilt, each provided a level of induced resistance to each of Fusarium wilt of melon caused by *F. oxysporum* f. sp. *niveum* and of tomato caused by *F. oxysporum* f. sp. *lycopersici*, where half of each root system was exposed to one of the nonpathogens and other half in a separate pot was exposed to the pathogen.

The Fusarium wilt syndrome starting with infection and ending with a wilted plant has been worked out by Beckman (1987, 1990) for Fusarium wilt of banana caused by *F. oxysporum* f. sp. *cubense*. The pathogen, residing in soil as dormant chlamydospores, is stimulated by root exudates to begin growth, similar to any other pathogen existing dormant in soil waiting for a host root to grow near it. The pathogen enters the root behind the root tip, in the region not yet differentiated into vascular tissue. As the xylem forms in the region of maturation, the pathogen is now positioned to begin its journey to the top of the plant. It does this by producing microconidia that are carried upward with the water stream in the xylem. Xylem end walls are perforated, so they function like sieves. When a microconidium reaches an end wall, it germinates, grows through an opening in the end wall, and produces more microconidia that are then carried upward in the water stream to the next end wall. This process is repeated until the

pathogen reaches the petioles and ever-smaller veins in the leaves, which is when the plant begins to wilt and then die. The host, meanwhile, is not passive to this process. It reacts by attempting to wall off the pathogen by formation of gels and tyloses within the xylem. Susceptibility is when the pathogen stays just ahead of the walling-off or occlusion process, meaning that the host essentially plugs up its own water-conducing system. The pathogen now distributed inside the dead plant is positioned to begin its saprophytic survival by colonizing and taking possession of its dead host from the inside out. Resistance is when the occlusion reaction is fast enough to stay ahead of the invading pathogen, thereby walling it off near the beginning of its journey to the top.

Nonpathogenic *Fusarium* spp., including or especially nonpathogenic *F. oxysporum*, are ubiquitous in cultivated soils, living mainly as colonists of root cortical tissues, much like endophytes, where they are poised to more fully colonize the root ahead of any competition once the root dies. Like the endophytes of leaves, these root inhabitants are limited to root cortical tissues, presumably by host defenses. A Fusarium wilt-suppressive soil may include the presence within that soil of strains or subspecies of nonpathogenic *F. oxysporum* that not only respond preemptively to the same carbon, energy, and other signals from host roots that trigger growth of the pathogen but also triggers a rapid resistance response of the host in time to wall off the pathogen as well as the non-pathogen. A moderately resistant cultivar might then perform more like a fully resistant cultivar, as was found after four successive plantings of the variety of watermelon moderately resistant to wilt caused by *F. oxysporum* f. sp. *niven* (Larkin *et al.*, 1993).

Although a single mechanism is not likely to explain the many examples of Fusarium wilt-suppressive soils worldwide, the one common and consistent denominator is a clear association with nonpathogenic strains of *F. oxysporum*. Moreover, a study of the genetic diversity of nonpathogenic *F. oxysporum* revealed similar populations in two fields several kilometers apart in the Chateaurenard region of France known for its soils suppressive to Fusarium wilts, as well as evidence that the same genotypes occur and have remained a stable component within the diversity of genotypes of nonpathogenic *F. oxysporum* within these fields over time (Edel *et al.*, 2001) in the same way that long-life soils in Central America have remained stable over time.

Development of Suppressive Soil with Crop Monoculture

One of the earliest documented example of a soil being conducive and then suppressive to a pathogen with continuous monoculture of the host is Phymatotrichum root rot of cotton and other susceptible hosts. *Phymatotrichum omnivorum* has a wide host range, although economically it has been particularly important on cotton in Texas and alfalfa in Arizona. The disease on cotton occurs as patches that become gradually larger but then disappear, according to observations by Scofield (1919); McNmara *et al.* (1931) confirmed the observations of Scofield but noted further that disappearance of the patches in stands of cotton begins in the centers. Similarly in alfalfa, the disease begins as patches that gradually become rings, much like a fairy ring (King, 1923); King (1923) confirmed that alfalfa plants recover over time starting in the center but showed further that cow peas, in spite of their susceptibility to *P. omnivorum*, remained healthy for the entire season when planted into the center of a Phymatotrichum ring in a stand of alfalfa. Apparently, no further research has been done to explain why the rings (or spots) disappear, reappear, or disappear starting at the center.

Common scab of potatoes caused by *Streptomyces scabies* was observed early in the last century to decline with potato monoculture. In plots subjected to different rotations under irrigation in Nebraska during the period 1912–36, with the incidence and severity of common scab recorded for potatoes each year starting in 1929, scab was recorded initially as severe or pitted but then became nonexistent where potatoes were grown continuously. In contrast, both severe and pitted occurred in each of plots where potatoes were grown in a sugar beet/potato, oats/potato, or corn/potato rotation (Goss and Afanasiev, 1938); Weinhold *et al.* (1964) similarly recorded a decline in common scab of potato grown since 1949 as a monoculture under irrigation near Shafter, CA, compared with potato/cotton, potato/sugar beet, and potato/barley rotations. Scab continued to increase on continuous potatoes early in the study until the eighth year and then steadily decreased whereas scab on potatoes grown in rotation continued to increase on each potato crop until 1961, during which there was less scab on potatoes grown in monoculture than those grown in a 2- or 3-year rotation.

Working with common scab of potatoes in the irrigated central Washington State, Menzies (1959) not only associated soils suppressive to *S. scabies* with long-term production of potatoes, what he referred to as 'old' fields, but also made the first transfer of an antagonistic microbiota of a pathogen-suppressive soil from an old field to soil from a 'new' field. Both fields were arid lands, essentially desert lands, brought into production with irrigation and conducive to scab, with the 'new' fields brought into production most recently. Only 10% suppressive soil plus 1% alfalfa meal was required to transfer the suppressiveness, whereas 1% alfalfa meal alone had no effect. It is highly unlikely that the mixing of 10% of one soil with 90% of another soil would change the physical and chemical properties sufficiently to account for transferability of the suppressiveness. Autoclaving eliminated the suppressiveness, further confirming a microbiological basis for the suppressiveness and pointing to an example of specific suppression.

An experimental plot of monoculture potatoes maintained at Grand Rapids, MN for screening potato germplasm for resistance to common scab of potatoes could no longer be used after approximately 20 years because of the soil having become suppressive to scab (Lorang *et al.*, 1995). Soil transferred from the scab-suppressive plot to a scab-conducive plot near Becker, MN also transferred the suppressive factor (Bowers *et al.*, 1996). This 'factor' was subsequently shown to involve the buildup of nonpathogenic *Streptomyces* species or weakly pathogenic *S. scabes* inhibitory to the more pathogenic *S. scabies* (Liu *et al.*, 1996; Lorang *et al.*, 1995). A nonpathogenic strain of *S. diastatochromogenes* and a weakly pathogenic strain of *S. scabies*, each shown to inhibit the highly pathogenic strains by production of an antibiotic (Liu *et al.*, 1996), were

mixed into an *S. scabies*-infested scab-conducive soil with a vermiculite/oatmeal/broth carrier contained in pots held outdoors and each planted to potatoes for four consecutive years. Even the lowest rate (1% by volume) of suppressive *Streptomyces* strains provided significant control of scab already in the first year and continued to provide scab control on the subsequent three consecutive crops of potatoes. The carrier alone mixed into the soil and planted to potatoes provided no control of scab (Liu *et al.*, 1995).

The evidence is clear that scab decline results from a shift in the makeup of the *Streptomyces* populations from highly pathogenic but low producers or nonproducers of antibiotics to weak or nonpathogenic strains inhibitory to the pathogenic strains by production of antibiotics. The outcome is apparently an example of the advantage conferred on strains with ability to inhibit their nearest relatives likely to occupy the same ecological niches and depend on the same nutrients. However, from the practical standpoint, the great majority of potato production worldwide depends on crop rotation and even soil fumigation to control nematodes and other soilborne plant pathogens. Monoculture potatoes might only be practiced today on a small scale, such as in private garden plots.

One of the best documented examples of a disease decline in response to a specific cropping system, but not necessarily the same crop grown in monoculture, is from a long-term cropping systems study conducted with dryland crops near Ritzville, WA (269 mm annual precipitation) (Schillinger and Paulitz, 2006, 2013). This location is well within the rainfed semiarid region described above as the Pacific Northwest Columbia Basin with a high frequency of phenazine-producing pseudomonads in the rhizosphere of wheat (Mavrodi, 2012). The study was launched in 1996 using spring and winter wheat, spring barley, yellow mustard, and safflower, all direct seeded (no till) in a field that had been managed for years with winter wheat alternated with a year of fallow and conventionally tilled. A disease known as 'bare patch' due to severe root rot caused *R. solani* AG-8 began to appear in all crops in the third year of the study and continued to increase in both size and numbers as documented by GPS measurements until the eighth year of the study. During years 5–7, bare patches occupied as much as 18% of land area cropped to wheat or barley. Interestingly, although wheat and barley are equally susceptible to this pathogen, with barley being possibly more susceptible than wheat, 15% of the area in monoculture spring wheat were bare patches during years 6–8 of the study compared with 7% of the area in bare patches in plots managed as a 2-year rotation of spring barley/spring wheat. Thereafter, the patches began to disappear in both monoculture wheat and the wheat/barley rotation until year 11 when the total area of wheat and barley in patches was less than 1%. No patches were present in years 12–15 when the study was discontinued.

Rhizoctonia root rot caused by *R. solani* AG-8 and the less pathogenic *Rhizopus oryzae* (Ogoshi *et al.*, 1990) became more important, including as bare patches in rainfed wheat and barley, in both the northeastern Oregon, eastern Washington, northern Idaho, and the Southern Australian wheat belt with the adoption by growers of the no-till or direct seeding for dryland cereals. The study by Schillinger and Paulitz (2006, 2013), done in the field over a 15-year period, is among the best documented examples of disease decline and the first to document disease decline in response to a 2-year rotation using a no-till (direct seed) planting system. Enduring a decade or longer of bare patches and potentially 15% lower yields during peak years of the disease, not to mention the added cost of controlling weeds in the bare patches, might seem uneconomical as an approach to manage Rhizoctonia root rot of cereals. However, many growers in the rainfed Inland Pacific Northwest and the Southern Australian wheat belt, where this disease is most important, already converted into a direct-seed system 20 years ago and must already be benefiting from this natural biological control. Roget *et al.* (1999) documented a suppression of Rhizoctonia root rot after severe disease in a wheat-based cropping systems in Southern Australia within approximately 15 years of direct seeding in the field. Timely management of the volunteer (self-sown) cereals, known as the 'green bridge,' has also played an important role in lowering the pressure of this disease (Roget *et al.*, 1987; Smiley *et al.*, 1993). Whether it is better management of the green bridge or disease decline in response to increases in phenazine-producing pseudomonads-intensive direct-seeded cereals, Rhizoctonia root rot and particularly the bare patch version of this disease have become rare occurrences compared with the 1980s and 1990s in both the Pacific Northwest and Australia.

Lucas *et al.* (1993) demonstrated the development of soil suppressive to Rhizoctonia root rot caused by *R. solani* AG-8 in each of two wheat field soils from NE Oregon, each planted five successive times to wheat in greenhouse pots, with additional inoculum of the pathogen added with each planting. Of particular interest in their study was that the soils only became suppressive to root rot caused by *R. solani* AG-8 in response to inoculum of *R. solani* AG-8 but not to *R. oryzae*, pointing to this disease decline as an example of specific suppression.

Hyakumachi and Ui (1982) documented a decline of Rhizoctonia root rot with sugar beet monoculture on Hokkaido, Japan. Following up on observations by a local sugar beet company that severe Rhizoctonia root rot one year would be followed by a healthy sugar beet crop in that same field the next year, they designed a field experiment that included monoculture sugar beets in plots with the pathogen introduced and reintroduced in successive years. Rhizoctonia root rot was consistently severe in the first year and absent in the second and subsequent years of monoculture, including in plots with the pathogen reintroduced each year. A single year of severe disease was enough to convert the soil from conducive to suppressive to Rhizoctonia root rot of sugar beet.

Another case of soil suppressive to Rhizoctonia root rot of sugar beet following severe disease in a previous crop was documented in the Netherlands and shown by Mendes *et al.* (2011) to be an example of specific suppression. The suppressive soil greatly limited Rhizoctonia root rot on sugar beet seedlings in contrast to a similar soil from the margin of the field that allowed heavy seedling mortality under the same conditions and dose of *R. solani* inoculum. Heat treatment of the suppressive soil at 50 °C partially eliminated suppressiveness, and heat treatment at 80 °C and γ-radiation totally eliminated suppressiveness. Mixing 10% suppressive soil with 90% conducive soil partially restored suppressiveness.

Mendes *et al.* (2011) used a metagenomic approach to characterize the rhizosphere microbiome for disease-suppressive bacteria. Metagenomic deoxyribonucleic acid (DNA) was isolated from the rhizosphere microbiota of sugar beet seedlings grown in suppressive soil, conducive soil, conducive soil amended with 10% suppressive soil, suppressive soil heat-treated at 50 °C, and suppressive soil heat-treated at 80 °C. A total of 33 346 bacterial and archaeal operational taxonomic units (species equivalents) were detected in the sugar beet rhizosphere microbiome, with no significant differences in the number of bacterial taxa detected among the respective treatments. However, a comparison of the relative abundance of different taxa revealed six clusters corresponding to the six treatments, suggesting that relative abundance of certain bacterial taxa plays a bigger role in suppressiveness than the presence of specific bacterial taxa. The bacterial phyla Proteobacteria (includes Pseudomonaceae, Xanthomonadales ,and Burkholderiaceae), Firmicutes (includes Lactobacillaceae), and Actinobacteria all were more abundant in suppressive soil than in conducive soil as well as in suppressive soil amended with 10% conducive soil. The 50 °C heat treatment would have eliminated the Proteobacteria and Firmicutes but possibly the 80 °C treatment would have been needed to eliminate the Actinobacteria because these bacteria form spores.

Mendes *et al.* (2011) used a high-density 16S ribosomal DNA oligonucleotide microarray, known as the PhyloChip, to further identify bacterial species and genes involved in disease suppression. Interestingly, results of this culture-independent approach to identification of suppressive taxa compared well with a more traditional culture-dependent approach. Of 111 antagonistic bacteria isolated from suppressive soil, 104 were members of the Pseudomonadaceae. Based on DNA fingerprinting by BOX-PCR, these isolates were grouped into 10 closely related (94–98% identity) haplotypes. Three haplotypes represented by 38, 21, and 37 isolates accounted for 90% of the antagonistic bacterial isolates from the *Rhizoctonia*-suppressive soil. When representative isolates of the three haplotypes were tested in sugar beet seedling assays, one provided biological control of *R. solani*. Two mutants of this strain, produced by transposon mutagenesis, showed to no longer protect sugar beet seedlings against infection by *R. solani*, although they colonized the rhizosphere to the same extent as the wild type. The mutated gene was shown to be a nonribosomal peptide synthase gene with 69% identity with the *syrE* gene of *Pseudomonas syringae*. Subsequent genetic analyses revealed a two-gene cluster predicted to encode a chlorinated lipopeptide.

This research takes the study of pathogen-suppressive soils to a new level using the new tools of metagenomic analysis combined with traditional culture techniques. Although the authors cautioned against ruling out other organisms in the suppression of Rhizoctonia root rot of sugar beet, the fact that this one haplotype along with two others out of 10 with 94–98% identity were members of the Pseudomonadaceae is consistent with the putative causes of other examples of suppressive soil. For example, fluorescent pseudomonads were shown to play a primary role in the suppression of black root rot of tobacco caused by *Thielaviopsis basicola* in a soil cropped 24 years to monoculture tobacco (Stutz *et al.*, 1986). Of several potential mechanisms of inhibition investigated, work with *P. fluorescens* CHA0 (now *Pseudomonas protegens* CHA0) obtained from the suppressive soil and one of the premiere model strains for fundamental research pointed to the importance of the antibiotic DAPG in this natural suppression (Keel *et al.*, 1992). The decline of take-all caused by *G. graminis* var. *tritici* discussed in detail below is similarly related to the buildup of specific genotypes fluorescent pseudomonads in the *P. fluorescens* complex (now *Pseudomonas brassicacearum*) with ability to produce the antibiotic DAPG. TAD has become another model for research on understanding the microbiological and molecular bases for the specific suppression responsible for disease decline with continued monoculture of the host and an important source of clues as to the success of intensive cropping (Cook, 2007).

Take-All Decline

Of all the examples of disease decline with continuous monoculture of the crop, none have revealed more about the microbiological mechanisms although serving as a practical means to root disease management than the decline of take-all (*G. graminis* var. *tritici*) with continuous monoculture of wheat or wheat/barley sequences. Fellows and Ficke (1934) working in Kansas were possibly the first to report the appearance of take-all patches in the second crop of wheat, more patches in the third and possibly the fourth crop of wheat, followed by the disappearance of take-all patches with continuous monoculture of wheat. Glynne (1935) working in the United Kingdom noted the same pattern of increase and then decline in take-all with continuous wheat monoculture. However, the first clear documentation of a microbiological basis for TAD was by Gerlach (1968) working with polder soils in the Netherlands newly reclaimed from the North Sea and planted first to reed grass and then continuous wheat. Take-all increased in the first two or three crops but then declined to an economically tolerable level in subsequent crops. He showed in greenhouse studies that a given amount of inoculum produced only mild take-all when introduced into polder soils that had entered TAD but severe take-all in polder soils not yet into TAD. He showed further that the suppressiveness was eliminated by heat treatment of the soil.

Following the lead of Menzies (1959), and working with both arid virgin (soils not yet brought into cultivation) and long-term wheat monoculture soils from the Columbia Basin of eastern Washington, Shipton *et al.* (1973) showed that the suppressiveness to take-all in long-term wheat monoculture soils was transferable with only 1% (by weight) to a virgin soil, and that the suppressiveness was eliminated by heat treatment of moist soil at 60 °C for 30 min using a steam–air mixture. Cook and Rovira (1973) used the experimental system of Shipton *et al.* (1973) to demonstrate further that suppression of the take-all pathogen occurred in the rhizosphere of wheat and not in the bulk soil and provided the first evidence that root-associated fluorescent pseudomonads played a role in the suppression.

Probably no experiment showed more conclusively the existence of an agent or agents responsible for TAD than the results of a field trial conducted over the years 1971–73 by R.J. Cook and P.J. Shipton and reported by Baker and Cook

(1974). Soil from each of three long-term wheat fields along with corresponding soils from each of three close by non-cropped sites, either in grasses or native vegetation (six soils in total), were transported in 120 l containers from eastern Washington to a Washington State University (WSU) research farm in western Washington. There the soils were each applied to the surface of four separate replicate plots, each 1.3 m by 3.3 m and mixed to a depth of approximately 15 cm with a rotovator. Two additional treatments included the local soil mixed in and rotovation only (no added soil). The entire experimental area had been fumigated with methyl bromide before adding the soils to eliminate any native pathogens or resident antagonists. The plot area as part of a larger area was seeded with a standard grain drill with wheat seed mixed with autoclaved oat grains colonized by the pathogen as a source of inoculum. The wheat that grew from that sowing was harvested and the entire plot area reseeded that same fall with only wheat. This harvest/reseed cycle was repeated a third time.

Take-all was uniformly severe in the first year but was almost completely absent in the second year, specifically in the four replicate plots that received soil from a 12-year-wheat-monoculture field of irrigated wheat from near Quincy, WA (**Figure 2**). By the third sowing, TAD has occurred uniformly over the entire experimental site.

A second wheat monoculture experiment was started in the fall of 1968 on 1 ha plot on the WSU experiment station near Lind, WA. The site had been managed for several decades with dryland winter wheat alternated with a year of fallow but was sprinkler irrigated to supplement the average annual precipitation of 25 cm with another 25 cm needed for annual cropping. Take-all is present but detected only by careful examination of roots of dryland wheat alternated with fallow; however, it develops into the classic disease (**Figure 2**) with continuous wheat under irrigation. In the plot near Lind, take-all appeared in the third and subsequent years of monoculture wheat, was most severe in the seventh year of monoculture wheat when the difference between fumigated and non-fumigated plots was striking, but then declined until, by the 15th year, there was no visible difference between fumigated and nonfumigated plots (**Figure 3**).

Bacteria cultured from the rhizosphere of wheat growing in suppressive soils in the presence of the take-all pathogen, including soil from the Lind plot following TAD, revealed strains of fluorescent pseudomonads with ability to produce phenazine-1-carboxylic acid and 2,4-diacetylploroglucinal, as shown in the recent comparison of antibiotic-producing pseudomonads in the rhizosphere of irrigated and rainfed wheat (O. Mavrodi *et al.*, 2012). Both strains inhibited take-all when introduced on seeds planted into soil infested with the take-all pathogen. Similarly, mutant strains no longer able to produce antibiotic phenazine-1-carboxylate (Phz+) or Phl+ lost ability to protect wheat against take-all, and both mutants were restored in ability to protect against take-all when the respective mutant genes were complemented with a wild-type gene (Weller *et al.*, 2002). A seven-gene locus shown to account for biosynthesis of phenazine-1-carboxylic acid (Mavrodi *et al.*, 1998) and a six-gene cluster shown to account for biosynthesis of Phl (Bangera and Thomashow, 1999) served as sources of marker genes for quantification of the respective populations in the wheat rhizosphere by PCR analysis. The results showed that the subpopulations of Phl+ fluorescent *Pseudomonas* species but not the subpopulation of Phz+ rhizosphere-inhabiting bacteria could account for TAD under continuous wheat monoculture in Washington State (Raaijmakers *et al.*, 1997). These results were confirmed for take-all suppressive soils in the Netherlands (Souza *et al.*, 2003).

The threshold population of Phl+ strains of *Pseudomonas* spp. naturally present in the rhizosphere of wheat growing in soils that had undergone TAD was consistently in the range of log 5–6 colony forming units (CFU) per g fresh weight of root (Raaijmakers and Weller, 1998; Raaijmakers *et al.*, 1997).

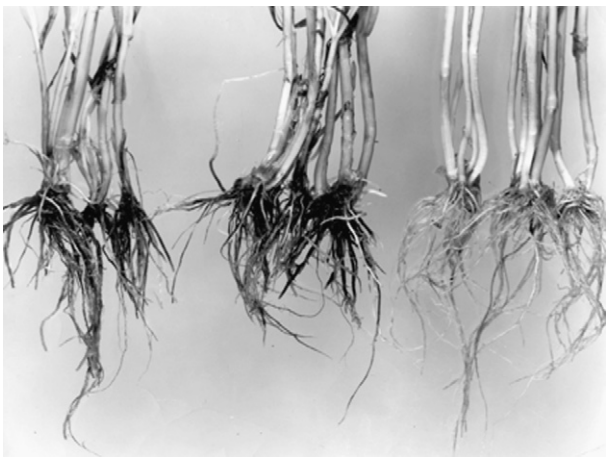

Figure 2 Field transfer of a factor or factors suppressive to take-all of wheat caused by *G. graminis* var. *tritici*. These plants came from plots in the second year of wheat monoculture where, before planting in year one, the plots were amended to a depth of 15 cm by rotovation with soil from an eastern Washington irrigated wheat field in the twelfth year of continuous wheat monoculture (far right), soil from a nearby virgin area under native vegetation predominated by sage brush (center) and no added soil (check, far left). All wheat plants were healthy in the third year of wheat monoculture. The one-time added soil amounted to approximately 0.5% by weight.

Figure 3 Winter wheat in the fifteenth year of continuous wheat monoculture under irrigation near Lind, WA. The man is standing on the border between a plot fumigated with methyl bromide before planting the previous fall (the man's left) and nonfumigated.

Elimination of this subpopulation coordinately eliminated suppression, and its restoration to >log 5 CFU per g root by mixing TAD soil with conducive soil and planting wheat coordinately restored suppression of take-all. The amount of Phl produced in the rhizosphere of wheat by a Phl-producing strain ranging between log 6 and log 7 CFU per g root was calculated at 0.62 ng 10^{-5}CFU (Raaijmakers *et al.*, 1999).

Interestingly, the D genotype (now *P. brassicacearum*) has been identified as the dominant strain in the rhizopsphere of wheat following TAD in both Washington State but a different genotype dominates in the Dutch TAD soils (Weller *et al.*, 2002). One particularly rhizosphere-competent strain, *P. brassicacearum* Q8r1-96, was shown to maintain the necessary threshold population for take-all suppression in natural soil when introduced as a seed treatment.

Logically, it should be possible to 'jump start' or enhance TAD by introduction of *P. brassicacearum* Q8r1-96 as a seed treatment in the same way the earlier introduction of soil from the 12-year continuous-wheat-monoculture field served to jump start TAD at the site in western Washington in the early 1970s. Field trails showed that yields can be increased by seed treatment with single and combinations of strains on wheat after wheat (Cook *et al.*, 2000). However, turning this approach into a commercial technology would require a formulation suitable for commercial use and tests required of the US Environmental Protection Agency for registration of the product as a biopesticide. The alternative strategy in use, knowingly or unknowingly by growers worldwide, is to maintain intensive cereal grain sequences. In the Inland Pacific Northwest, for example, growers use a 2-year rotation of winter wheat alternated with spring wheat or a 3-year rotation of winter wheat/spring wheat/spring barley, both of which maintain an effective level of take-all suppression.

To date, at least 22 Phl+ genotypes of the *P. fluorescens* group have been identified worldwide based on polymorphisms in one of the six biosynthetic genes required for biosynthesis of this antibiotic (De La Fuente *et al.*, 2005); however, the number of genotypes is no doubt greater. Of particular interest is that certain genotypes of Phl+ *Pseudomonas* spp. seem to dominate in certain cropping systems, including in response to certain crop monocultures. For example, on the experimental station of North Dakota State University where each of flax and wheat were grown in monoculture for more than 100 years, roughly 80% of the Phl+ fluorescent pseudomonads were the F and J genotypes in the rhizosphere of flax, whereas 76% of the Phl+-producing fluorescent pseudomonads were the D genotype (*P. brassicacearum*) in the rhizosphere of wheat (Landa *et al.*, 2005) – the same genotype identified in the rhizosphere of monoculture wheat in Washington state. Moreover, population of *P. brassicacearum* on wheat in the Fargo plot exceeded the log 5.0 threshold associated with take-all suppression.

Approximately 50% of US cropland is planted to corn and soybeans each year, as continuous corn in a 2-year corn–soybean rotation. The question arises as to whether any stable cropping system involving the same two crops grown in the same field for decades might enrich for specific genotypes of antibiotic-producing *P. fluorescens* suppressive to soilborne pathogens of one or both of these two crops? McSpadden Gardner *et al.* (2005) working in Ohio found Phl-producing *P. brassicacearum* in the rhizosphere of both corn and soybeans in all 15 counties sampled. Further, it was the most abundant of seven genotypes identified, exceeding log 3.4 on 77%, 84%, and 81% of corn plants sampled in years 2001, 2002, and 2003, respectively, and 78%, 67%, and 52% of soybean plants sampled during those three years, respectively. The average annual yield of soybeans and especially corn have continued to increase over the past 75–80 years, with the credit given as approximately 50% to genetics and 50% to management. Possibly some credit should also go to suppression of known or unknown root diseases by antibiotic-producing strains of *Pseudomonas* in the corn and soybean rhizospheres.

Reverse Fortunes of the Apple Replant Disease

Apple, like other orchard or perennial crops, is a monoculture subject to root diseases like any other crop grown without benefit of crop rotation. However, the real manifestation of root disease on apple becomes evident only when the trees are removed and the same site replanted with young apple trees, a phenomenon known as the apple replant disease. Mazzola (1995) showed for Washington apple orchards that the replant disease is due to a complex of root pathogens, including *Cylindrocarpon destructans, Phytophthora cactorum, R. solani* AG-5, and *Pythium* spp. However, unlike the examples of disease decline with crop monoculture discussed above, soils new to apples are suppressive to the root disease complex but become conducive by the fourth or fifth year of growth, in contrast to old orchard soils that are conducive already in the year of replanting.

The introduction of inoculum of *R. solani* AG-5 into soils collected from sites new to apples and ranging from the first to the fifth year of growth showed that the soil was suppressive in the first and second year but became conducive at the start of the third year. Concomitant with the loss of suppressiveness, populations of *Burkholderia cepacia* and *Pseudomonas putida* decreased, whereas populations of *P. syringae* and *P. fluorescens* biovar C increased. A separate study showed that a *P. putida* population similar to that in first-year apple growth controlled the replant disease on apple seedlings (Mazzola, 1999); Mazzola and Gu (2000a) found in greenhouse experiments that growing wheat resulted in a suppressiveness to the apple replant disease similar to soil not previously planted to apples. This has led to a practice of rotating old apple orchard soil to wheat before replanting apple (Mazzola and Gu, 2000b). The older the trees when infected, the more they can tolerate root infections; moreover, whatever damage does occur is more subtle compared with young trees with roots infected the year they are planted.

Concluding Comments

Although research on the molecular biology and biochemistry of host–plant defenses against above-ground diseases remains focused on host–pathogen interactions, research on the molecular biology and biochemistry of plant–host defense against soilborne pathogens is focused almost entirely on plant-associated microorganisms responsible through competition,

production of antibiotics, and induced host–plant resistance and known as pathogen-suppressive soils. Indeed, to understand the molecular and biochemical mechanisms involved in the *Gaeumannomyces*/*Pseudomonas* interaction responsible for TAD with continuous wheat monoculture is exceeded as a soil microbiological phenomenon only by the understanding of the molecular and biochemical processes involved in nitrogen fixation by *Rhizobium* spp. Furthermore, although the exploitation of nitrogen fixation in agriculture depends more on naturally occurring resident rhizobia than on their introduction with the seed at each planting, exploitation of TAD depends entirely on resident Phl+ genotypes of the *P. fluorescens* group. TAD is a model for similar studies of the mechanisms of pathogen suppression, especially the more intriguing and potentially exploitable examples of disease decline with crop monocultures, double cropping, and 2-year crop rotations.

Of the two types of pathogen-suppressive soils – general and specific suppression – only specific suppression can be managed with any degree of certainty and then largely or entirely by choice of the cropping system. Amending soil with large quantities of compost or other biomass is about the only management option available to reliably increase the level of general suppression. This may be part of the long-term success of direct seeding where crop residue is left to decompose on the soil surface or is mixed superficially into the top few centimeters of soil with the planting operation. In many developing countries, however, rather than adding or conserving the crop residue *in situ*, the trend has long been to remove it for fuel or animal feed. Current research and plans to produce biofuels from corn stalks and wheat straw will need to consider the value of this resource in maintaining an active and pathogen-suppressive soil microbiota of the general type.

There is a risk in depending over a long term on suppression of a specific disease in response to a specific cropping system. The level of disease suppression, being biologically based, will likely vary from year to year depending on local conditions, thereby allowing some level of disease in some years. Shifting the field to a different cropping system can also cause the soil to again become conducive, thereby requiring one of more disease outbreaks in order to restore suppressiveness when returning to a crop susceptible to that disease. Further, most crops are subject to infection by three of four root pathogens, and suppression of one can expose the root system to greater damage from one or two others. After 15 years of irrigated monoculture wheat and essentially full decline of take-all on the WSU research farm near Lind (described above), Rhizoctonia root rot caused by *R. solani* AG-8 appeared in the sixteenth year and increased to a maximum level of severity in the nineteenth year before stabilizing. No attempt was made to document its decline with continued wheat monoculture as done in the study near Ritzville. Dependence on a specific suppression should be considered as only one of several components of an integrated system needed to manage a mixture and not just one root disease.

Crop rotation is clearly the most dependable means to control soilborne pathogens of agronomic crops that cannot justify the expense of fumigation or solarization. This fact notwithstanding, with the need for specialized and expensive equipment to plant and harvest a grain crop, potatoes, sugar beets, or alfalfa hay, together with the need for an efficient and reliable marketing infrastructure, leaves most modern farm businesses little choice but to specialize in the production of two crops, rarely more. Likewise, more and more land planted to agronomic crops, such as corn, soybeans, cereal grains, and canola, are direct seeded rather than tilled as was done for decades, to reduce fuel costs, improve soil quality, and store more carbon that otherwise or eventually is released as a greenhouse gas. Direct seeding of wheat was shown in the early years of adoption to favor both take-all and Rhizoctonia root rot, requiring some form of soil disturbance even if only in the seed row. The fact that both of these diseases have been documented by careful and long-term studies to decline in direct-seed cropping systems speaks well for what might also be happening or has already happened with other crops managed in short rotations and even without benefit of crop rotation.

Plant Health Management: Soil Fumigation

DO Chellemi, US Department of Agriculture, Fort Pierce, FL, USA

Published by Elsevier Inc.

Introduction

Soil fumigation is a form of soil disinfestation that involves the application of volatile chemical compounds (fumigants) before planting to rid the soil of plant pathogens and pests. Other forms of soil disinfestation include steam sterilization, solarization (the use of clear plastic to heat soil), flooding, and anaerobic soil disinfestation (a combination of flooding and organic amendments). Soil fumigation is practiced on a wide variety of agronomic, fruit, nursery, ornamental, turf, and vegetable crops to control a broad spectrum of soilborne pests including plant pathogens, nematodes, insects and weeds. To be effective, chemicals used for soil fumigation must be extremely toxic to a wide range of organisms encompassing actinomycetes, bacteria, fungi, oomycetes, insects, nematodes, and plants (both seeds and vegetative material). Many popular chemical fumigants are halogenated organic compounds that disrupt basic cellular structure or functions via methylation of protein sulfhydryl groups, interference of the cytochrome-mediated electron transport chain, and/or direct attack on amino and hydroxyl groups. Soil fumigants are unique chemical pesticides. They are highly volatile, enabling them to disperse rapidly through the soil profile following application as a liquid. To achieve this, chemical fumigants should include a number of characteristics, including low boiling points and high vapor pressures; and they should posses a strong affinity to move through air spaces within the soil profile. Henry's law (K_H) constant is employed to measure the partition potential of a compound between the air and water phases. In general, K_H values $> 10^{-4}$ imply that compounds will diffuse more rapidly in the vapor phase and thus will move quickly through the soil profile when the soil is below 50% saturation.

Soil fumigants can be applied either through the irrigation system (drip or overhead) or directly into soil via metal shanks attached to a farm implement (**Figure 1**). Details on the principals and theory of soil fumigation have been reviewed extensively by Goring (1962) and Lembright (1990). Soil fumigation is a popular form of pest control because one chemical application can effectively replace the need for combined applications of soil fungicides, bactericides, nematicides and herbicides, resulting in a substantial financial savings to growers. Soil fumigation is also popular because one simple application can eliminate the need for more complicated knowledge-based pest management programs that require additional information acquisition and processing, decision making, and long-term land management programs such as crop rotation. Initially, an inexpensive method of soil disinfestation, soil fumigant costs have risen dramatically over the past 15 years and in the US can reach US$2766 per hectare and account for 15% of the total operating costs for vegetable production (University of Florida, 2009). Thus, soil fumigation is now typically restricted to high value, intensively managed crop production systems where large monocultures are repeatedly planting in same location, precluding the use of crop rotations or fallow periods to mitigate the build-up of soilborne pests. Another interesting side note is the contribution of soil fumigation, particularly using the chemical methyl bromide, to agricultural and ecological research. Through comparison of yields to fumigated soil, it has been used to access and optimize the performance of more sustainable crop management practices (Cook *et al.*, 2002). It has also been used in ecological field research to experimentally test ecological theories such as island biogeography (Simberloff and Wilson, 1969).

History

The first documented example of soil fumigation using volatile organic compounds dates from 1869, where Baron Paul Thenard applied carbon disulfide (CS_2) to French vineyards infested with the root parasite *Phylloxera vastatrix* (Rohart, 1876; Rommier, 1876). Eventually, over 50 000 ha of European vineyards where fumigated by the end of the nineteenth century. The origin of many chemical fumigants began as waste byproducts of industrial reactions.

A mixture of dichloropropene and dichloropropane (DD) was produced as a byproduct of the production of allyl chloride by Shell Company and presented a disposal problem until its nematicial activity was discovered by Walter Carter in Hawaii (Carter, 1943; Caswell and Apt, 1989). The fumigant methyl bromide, initially manufactured as a flame retardant in the 1920s, was produced as a precursor to safer fire retardants such as BCF and Halon 1211. The popular soil fumigant chloropicrin (trichloronitromethane, CCl_3NO_2) had a more

Figure 1 Traditional shank application of soil fumigants practiced in the southeastern US.

 doi:10.1016/B978-0-444-52512-3.00250-3

insidious origin before its introduction to agriculture. Chloropicrin, produced by the reaction of picric acid and bleach, remained largely a laboratory curiosity until World War I when it gained widespread use in chemical warfare, both a lachrymator and a lethal gas. At the closure of World War I, the US had stockpiled an estimated 36 million pounds of chloropicrin (Roark, 1934) and agricultural scientists begin to assess the surplus chloropicrin for insecticidal properties (Cotton and Young, 1929; Moore, 1918). By the late 1950s, soil fumigation with mixtures of chloropicrin and methyl bromide had become the standard soil disinfestation practice for high-value crops such as tomato and strawberry (Geraldson *et al.*, 1965; Wilhelm *et al.*, 1961), replacing other less effective soil fumigants. For 50 years, methyl bromide was widely used as a soil fumigant due to its low cost, ease of handling, performance under a wide range of soil and environmental conditions, low phytotoxicity, and broad range of activity. Globally, it was viewed as indispensable wherever intensive agriculture was practiced (Vanachter, 1975), and in the US a 1990s economic study estimated that a ban on the use of methyl bromide would cost producers and consumers more than US$1 billion annually (Anonymous, 1993).

Biological, Environmental, and Human Impacts

The same combination of acute toxicity and high volatility that make fumigants an effective soil pesticide can also increase the risk of field worker and bystander exposure, contamination of ground and surface water, and environmentally damaging atmospheric emissions, creating a contentious source of conflict between the agricultural industry and consumer and environmental advocates. The registration of ethylene dibromide, at the time one of the most abundantly used nematicides in the world, was suspended by the US Environmental Protection Agency (USEPA) after it was identified in ground waters of Arizona, California, Connecticut, Florida, Georgia, Massachusetts, and Washington (Federal Resister, 1983). A contaminant of DD was detected in municipal drinking wells located near former pineapple production fields on the Hawaiian islands of Kauai, Oahu, and Maui, prompting a voluntary withdrawal by the manufacturer (Oki and Giambelluca, 1987). Use of the popular soil fumigant 1,2-dibromo-3-chloroprane (DBCP) was suspended by the USEPA after it was discovered that one-third of male workers at a DBCP manufacturing plant in California were sterile (Thrupp, 1991). Later, a massive sterilization of approximately 1500 banana plantation workers in Costa Rica from DBCP was also documented (Thrupp, 1991). DBCP was also detected in the ground waters of Arizona, California, Hawaii, Maryland, and South Carolina. In 1991, metam sodium gained national attention when a train derailed spilling over 43 000 l into the Sacramento River, causing catastrophic damage to wildlife and the river ecosystem (Cantara Trustee Council, 2007; Brett *et al.*, 1995). Methyl bromide was identified as a significant ozone-depleting compound, and agricultural soil fumigation was implicated as a major anthropogenic source (Yagi *et al.*, 1993; WMO, 1994). Under obligations of the US Clean Air Act and the Montreal Protocol on Substances that Deplete the Ozone Layer (an international stratospheric ozone protection treaty) a scheduled phase-out of production and sale was initiated in developed countries (USEPA, 1993; UNEP, 1995). Since 1999, production and importation of methyl bromide in the US has declined from 25 500 to 434 metric tons. In Europe, registrations for 1,3-dichloropropene (1,3-D) and chloropicrin were canceled and production and sale of both fumigants were phased out between 2008 and 2012.

Current and Future Status

In the US, the number of chemical compounds registered for use in soil fumigation has diminished to chloropicrin, dimethyhl disulfide (DMDS), methyl isothiocyanate (MITC) generators (dazomet, metam potassium, and metam sodium), and 1,3-D. Their chemical properties have been extensively reviewed by Ajwa *et al.* (2003) and Ruzo (2006), and a generalized summary of their maximum-use rates and relative effectiveness to methyl bromide is available (Noling *et al.*, 2010). A comprehensive reevaluation of chloropicrin, DMDS, and the MITC generating compounds by the USEPA in 2010 led to additional regulations place on their use to increase protection of agricultural workers and bystanders. Some of the new regulations include increased buffer zones of untreated soil between the application sites and neighboring residences, detailed site-specific fumigant management plans, emergency preparedness and response notification, and formal applicator training programs administered by the fumigant registrants (USEPA, 2013). The additional compliance assistance and assurance measures will dramatically restrict the ability to apply soil fumigants, particularly in urbanized areas.

Recent trends in soil fumigation have focused on developing a set of good agricultural practices (GAPs) for fumigant applicators that, when adhered to, enhance the pest control efficacy of alternative chemical fumigants and minimize their environmental and human health impacts. Key features of GAPs include the use of improved application methods and technology to reduce fumigant application rates, improve the precision of fumigant placement within the soil profile, and restrict their atmospheric emissions. For example, low disturbance fumigant application equipment was developed using small vertical colters mounted forward of a soil bed press to improve the precision of fumigant delivery without disturbing the soil profile (**Figure 2**). The combined use of low-disturbance application equipment and a soil surface seal reduced cumulative atmospheric emission of 1,3-D by 21% and chloropicrin by 18% when compared to traditional shank applications (Chellemi *et al.*, 2012). An under-bed fumigator using winged steel shanks mounted behind large vertical colters was developed to deliver soil fumigants underneath existing plastic mulched beds without disturbing the integrity of the beds (**Figure 3**). Significant control of plant parasitic nematodes and weeds with reduced fumigant application rates was achieved when the under-bed applications were made 7 days after planting beds were covered with plastic film (Chellemi and Mirusso, 2006). New formulations of plastic film have been developed and used as tarps to retain fumigants in the soil following application by using layers of ethylene vinyl alcohol resins, nylon, or other polyaminides. A standardized approach for estimating their permeability to soil fumigants was developed and used to assess

their performance under a range of field and application conditions (Papiernik *et al.*, 2011). Total cumulative atmospheric emissions of chloropicrin and MITC were reduced to less than 5% of the material applied when low-disturbance application technology was combined with improved plastic films (Chellemi *et al.*, 2010). Also included in GAPs are the selective inclusion of specific soil and environmental conditions that mitigate the impact of fumigant emissions. They include soil moisture above field capacity and good soil tilth. Soil tilth is defined as the physical condition of soil as related to its ease of tillage, fitness as a seedbed, and its promotion of seedling emergence and penetration (Karlen, 2005). An illustrated comparison of two fumigated planting beds with contrasting levels of soil tilth is presented in **Figure 3**. Ranked in order of impact on the retention of fumigants in the soil are soil water content, soil tilth, the type of plastic film, and soil texture (Chellemi *et al.*, 2011). When GAPs are following during the fumigant application process, many soil fumigants can achieve a spectrum of pest control similar to methyl bromide while maintaining a high level of marketable yields (Ajwa *et al.*, 2002; Chellemi and Mirusso, 2006; Gilreath *et al.*, 1999; Locascio *et al.*, 1997; MacRae *et al.*, 2010).

Figure 2 Use of vertical colters to improve the precision of fumigant placement within the planting bed and to minimize disturbance of the soil profile.

Figure 3 Precision placement of fumigants under plastic mulched beds using vertical colters and winged steel shanks.

Figure 4 A comparison of raised plastic mulched beds prepared in soils with good tilth (left) and poor soil tilth (right).

By definition, soil disinfestation procedures are not sustainable because reinfestation of treated soil occurs during crop production, necessitating the reapplication of soil disinfestation procedures for future crops. Future trends in soil fumigation research will include ways to mitigate the impact of chemical fumigants on nontarget beneficial soil microbial communities as a means of extending the time intervals between fumigant applications (**Figure 4**).

Plant Health Management: Soil Solarization

J Katan, Hebrew University, Rehovot, Israel
A Gamliel, Institute of Agricultural Engineering, Agricultural Research Organization, Bet Dagan, Israel

© 2014 Elsevier Inc. All rights reserved.

Glossary

Biocontrol Reducing pest populations or limiting their activity by means of a living agent.
Integrated pest management A holistic approach to pest control, which also considers environmental issues.
Mulch Covering the soil with organic residues or plastic tarp.
Polyethylene Plastic material, frequently used as sheets in agriculture.
Soil disinfestations Treating the soil before planting for pest control, usually using drastic means.
Soil solarization Solar heating of soil for pest control, usually by use of a plastic mulch.
Solar heating Exposure to solar radiation to achieve elevated temperatures.

Introduction

Soilborne pests, including pathogens, arthropods, nematodes, weeds, and parasitic plants, cause heavy losses to all major crops by affecting both yield and quality. In severe cases, they may totally destroy the crop, forcing the farmer to use drastic and expensive control measures, abandon the land, or shift to less susceptible, but often less profitable crops. There is, therefore, a need to develop cost-effective control methods that are economically, environmentally, and technologically sound to ensure crop productivity and yield stability (Katan, 1996). An effective method of control also prolongs the use of available lands for crop production.

Soil disinfestation is one of the approaches for the control of root diseases that are especially common with intensive and high-value crops, for example, greenhouse and horticultural crops. It is a sophisticated, expensive, and effective approach of control that carries great advantages. The basic principle is to eliminate a wide spectrum of harmful organisms in the soil before planting, usually using drastic chemical or physical means. Although the main goal of soil disinfestation is to eliminate the major pests when their populations reach economically intolerable levels, additional (albeit initially unintended) benefits may also be obtained. The elimination of accompanying detrimental biotic and abiotic agents that have been accumulating in the soil throughout its long history of cropping is an example of such a benefit. However, because of the drastic nature of soil disinfestation, it may also have a harmful effect on nontarget biotic and abiotic components of the soil.

Soil disinfestation consists of four approaches. The first two – steaming and fumigation – were developed at the end of the nineteenth century. A third approach is soil solarization (also called solar heating). Biofumigation or biodisinfestation based on the incorporation of organic amendments under plastic mulch is a fourth approach that has gained interest in recent years.

The history of soil solarization has been summarized (Katan and DeVay, 1991; Gamliel and Katan, 2009, 2012). Many attempts have been made since ancient times to harness solar energy (as a heating tool) for pest control, in soil or in planting material, although until recently this was done by means other than the use of plastic material to enhance and prolong heating. Soil solarization as a preplant treatment for control was first described in 1976, based on studies carried out in the Jordan Valley in Israel (Katan *et al.*, 1976). From the beginning, solarization has been based on covering (mulching, tarping) the soil with transparent polyethylene sheets. This, in fact, represents a modernized application of old mulching principles, using technologies and materials that were not available back then. Today's technologies (and materials) enable more intensive and controlled soil heating and hence more effective and reproducible pest control. Soil solarization represents a shift from the classical use of plastic mulching of soil, because the latter is usually used during cool seasons to elevate low soil temperatures, thereby promoting plant development. With soil solarization, a bare soil is mulched during the hot season to further elevate its maximal temperature (Gamliel and Katan, 2012). Soil solarization is a hydrothermal process that brings about thermal and other physical, chemical, and biological changes in moist soil during, or even after mulching, which may eventually lead to pathogen control (Katan, 1981; Stapleton and DeVay, 1986).

In 1977, following the first publication of the method, American plant pathologists from Davis, California, reported the successful application of solarization for the control of *Verticillium dahliae* (Pullman and DeVay, 1977), indicating the potentially wide applicability of the soil-solarization method. Deep interest in the new soil-solarization approach and its rapid adoption are reflected by a bibliography listing 173 publications on the topic of soil solarization during its first decade, from 22 countries (Katan *et al.*, 1987). Since then, more than 1000 studies on the topic have been published, and soil solarization has been adopted or investigated in 74 countries, both developed and developing (**Figure 1**). Most of the studies have been carried out in relatively hot regions or countries, but important exceptions in cooler or humid regions, with various levels of success, are also known.

Principles of Soil Solarization

Soil solarization is a climate-dependent method that needs to be adapted to the specific region and season in which it is

applied. The basic principles are summarized as follows (Gamliel and Katan, 2012):

1. Moist soil is mulched with transparent polyethylene sheets (Figure 2). Soil mulching should be carried out during periods of long daylight, high temperature, and intense solar irradiation (preferably with little or no precipitation).
2. The best time for soil solarization, i.e., when climatic conditions are the most favorable, can be determined experimentally by mulching the soil and measuring the resulting temperatures. Meteorological data from previous years and predictive models (see below) further facilitate this task. Monitoring changes in the populations of native pathogens or intentionally introduced pathogen inocula as a bioassay is an additional approach to determining the effectiveness of soil solarization.
3. The soil should be kept moist to increase the thermal sensitivity of pathogens' resting structures and to improve heat conduction from the soil surface to its deeper layers.
4. The thinnest polyethylene tarp that can be used for mulching without being easily damaged (35–40 μm thickness) is recommended because it is less expensive, but just as effective as the thicker tarps. Because the upper soil layer is heated more intensely than the underlying ones, the mulching period must be long enough, usually at least 4 weeks, to achieve pest control at all desired depths. The longer the mulching period, the greater the depth of effective control. With growth substrates and soilless culture, where the depth is 10–20 cm, shorter periods of solarization might be sufficient.
5. Solarization heats the soil through a repeated daily cycle. Typical maximal temperatures are within the range of 45–50 °C and 38–45 °C at depths of 10 and 20 cm, respectively, although higher temperatures have been recorded in certain regions. At a depth of 30–40 cm, maximal temperatures are 35–40 °C and are maintained for longer periods of time, although they are reached later in the day (Figure 3). In solarized plots where effective disease and weed control has been obtained, the temperatures are 5–15 °C higher than those in comparable nonsolarized plots.
6. As with any disinfestation method, recontamination of the soil after termination of solarization, for example, by infected propagation material or infested soil or water, should be absolutely avoided.

Soil Solarization for the Mangement of Soilborne Pests

Many studies have been published since 1976 describing the control of a variety of pests by solarization. These include fungi, oomycetes, nematodes, bacteria, weeds, invasive plants, and arthropod pests, as described below, and even some unidentified agents. In most cases, disease control or reduction is accompanied by reduction in inoculum density, yield increase, or both (Figure 4). The most extensively studied pests have been fungi, oomycetes, nematodes, and weeds. Most of the studies were conducted under realistic field conditions (many under farm conditions); therefore, their relevance and applicability to real-life conditions are high. This situation came about because solarization can actually be carried out only under farm conditions; simulation studies for solarization are especially difficult to carry out. The number of soilborne pests effectively controlled by solarization is very large, exceeding that of pests not controlled by solarization. Some pathogens that are highly sensitive to solarization, for example, *V. dahliae* and species of *Phytophthora*, were effectively controlled in most studies, whereas the level of control of moderately heat-tolerant pathogens, such as *Sclerotium rolfsii*, varies from site to site. Certain pathogens and weeds, however, are not effectively controlled by solarization, such as the heat-tolerant fungi of the genera *Macrophomina* and *Monosporascus*. This is not surprising as no single control method can be expected to be effective against all pests.

The following are examples of responses of various pathogens, with various crops, to soil solarization (Katan and DeVay, 1991; Gamliel and Katan, 2012; McGovern and McSorley, 2012; McSoreley and McGovern, 2012). It should be emphasized that these are based on studies carried out under various climatic conditions and with different cropping systems; therefore, any generalization has to be made with caution.

Figure 4 Commercial application of soil solarization to control broomrape in carrots. The small area on the left with stunted plants indicates a nonsolarized plot. Reproduced from Gamliel, A., Katan, J. (Eds.), 2012. Soil Solarization: Theory and Practice. St Paul, MN: APS Press.

The list of fungal pathogens that are frequently effectively controlled by solarization is large and includes, among others: various formae speciales of *Fusarium oxysporum*, for example, *basilici*, *lactucae*, *melonis* and *vasinfectum*, *Phytophthora* spp., *Pythium* spp., *Sclerotinia sclerotiorum*, *Sclerotium cepivorum*, *V. dahliae*, and *Rhizoctonia solani*. Results with *F. oxysporum* f. sp. *radicis-lycopersici* and *F. oxysporum* f. sp. *dianthi* have been variable.

The bacterial pathogens *Clavibacter michiganensis* subsp. *michiganensis*, *Streptomyces scabies*, and *Agrobacterium tumefaciens* are sensitive to solarization, whereas *Ralstonia solanacearum* seems to be more difficult to control.

Various plant parasitic nematodes are effectively controlled by solarization, including species of *Ditylenchus*, *Globodera*, *Heterodera*, *Paratylenchus*, *Pratylenchus*, *Rotylenchulus*, *Xiphinema*, and others. Soil solarization is especially effective at controlling *Ditylenchus dipsaci* and increasing garlic yield.

The effect of soil solarization in controlling *Meloidogyne* spp. root-knot nematodes is variable, apparently due to the fact that this nematode can survive in the deep, less heated soil layers, and later migrate up into the solarized soil layers.

Surprising as it may seem, the incidence of some foliar diseases (e.g., late blight of carrots and leaf spot of peanuts) has been reduced by solarization in certain cases. This might be attributed to a reduction of primary inoculum in the soil, as shown with *Botrytis* (Lopez-Herrera *et al.*, 1994), or to changes in the mineral content of the soil (Chen *et al.*, 1991) that, in turn, might enhance host–plant resistance. An interesting aspect of the effect of solarization on primary inoculum was shown by Philips (1990) with *Sclerotinia sclerotiorum*. Solarization not only reduced the sclerotial populations of this pathogen, but also reduced the ability of the surviving sclerotia to form apothecia. Induced resistance in plants growing in solarized soil has been reported (see Mechanisms of Pathogen and Disease Control and Plant-Growth Improvement). Solarization is also effective in controlling diseases and increasing the yield and biomass of plants grown in artificial growth substrates. For example, yield decline and growth retardation were evident in *Gypsophila* grown in either soil or artificial growth substrate under continuous cropping. In this study, *Pythium* spp. colonized the plant roots, and soil solarization nullified those phenomena and yield was increased by 17–97% (Gamliel *et al.*, 1993).

A long-term effect of solarization on disease control, yield increase, or both, for a second or even third season after the solarization treatment, has been observed in various regions and with a variety of crops (Hartz *et al.*, 1993; Satour *et al.*, 1989). The effect seems to be due to the drastic reduction in inoculum density and the induction of soil suppressiveness (see Mechanisms of Pathogen and Disease Control and Plant-Growth Improvement), which delays reinfestation of the soil by the pathogens. Combining solarization with other methods, especially biological control agents, should enable better and longer-lasting disease control, and may require less frequent application. The long-term effect has economic implications, in terms of reduced costs of control per crop.

Weed control is one of the observable results of soil solarization and can be used as an indicator of its effectiveness (Rubin, 2012). In general, annual weeds are more sensitive to solarization than perennial weeds. Purple nutsedge and *Melilotus* are usually not controlled by solarization. Soil solarization is also effective in reducing the seed banks of the invasive plant *Acacia saligna* despite the seeds' tolerance to heat (Cohen *et al.*, 2008). This seems to be connected with solarization's ability to break seed dormancy and then thermally kill the heat-sensitive seedlings. The parasitic weed *Orobanche* (broomrape) is also effectively controlled by solarization.

A comprehensive study of the effect of solarization on weeds was carried out in a Mediterranean climate at ICARDA in Syria (Linke, 1994). Of the 57 weed species from 25 families, 46 were reduced by solarizaton, 6 were unaffected, and 5 increased in numbers. Most annual weeds were controlled up to 100%. Low- to zero-control, or even stimulation, occurred with weed species having bulbs, heat-tolerant seeds, a deep-lying root system, or other perennial organs.

The possible mechanisms of weed control by solarization are direct thermal killing of seeds and biological control through weakening or other mechanisms, including breaking seed dormancy.

Soil solarization for weed control has advantages over herbicides in that it is a nonchemical method, there is no harmful residual effect, and its weed-killing effect may extend to deeper soil layers and may also reduce the weeds' seed banks.

Mechanisms of Pathogen and Disease Control and Plant-Growth Improvement

Understanding the mode of action of a management measure, as well as the accompanying biotic and abiotic processes, provides an important tool for optimizing pest control, predicting its efficacy, and minimizing undesirable side effects. Once the mode of action is known, the control measures can be better adjusted to the situation, thereby increasing the reliability and reproducibility of pest management. This is especially valid for soil disinfestation, which affects many biotic and abiotic soil components, and even more so for soil solarization, which is a climate-dependent method. The contribution of biological mechanisms toward pest control, beyond thermal killing of the pathogens, was already realized in early studies of soil solarization. Accumulating evidence shows that reduction of pathogen populations was recorded even under sublethal conditions from a climatic point of view, for example, in the lower soil layers. Many studies have shown that biological control processes are frequently induced or stimulated in solarized soil, thus contributing to pathogen and disease control. Below are some typical examples. The long-term effect of soil solarization was an indication that a beneficial shift in soil microbial activity might have occurred in the solarized soil, which indeed was shown in later studies.

The lower disease incidence among plants grown in solarized soils, as with any soil treatment, results from the effects exerted on each of the three living components involved in the disease – the pathogen, the surrounding soil microorganisms, and the host plant – as well as on the physical and chemical components of the environment which, in turn, affect the activities and interrelationships of these biotic components (Cook and Baker, 1983). Although these processes occur primarily during solarization, they may continue to various extents and in different ways after removal of the polyethylene sheets and planting. Soil solarization may affect inoculum density, inoculum potential, or both (Gamliel and Katan, 2009).

The mechanisms of biological control that may be created, stimulated, or suppressed by solarization can be connected with:

1. the inoculum existing in the infested soil – its reduction by direct microbial killing or by suppression of its saprophytic or pathogenic capacity;

2. suppression of reinfestation of the soil after termination of the solarization process, leading to induced soil suppressiveness;
3. induced host–plant resistance, namely, an effect via the plant system.

The above mechanisms have been demonstrated in various pathogen–plant systems. However, not all of the suggested mechanisms have to be realized in each system or even for the same pathogen.

A weakening effect results from exposing pathogen propagules to sublethal heating, which is not initially sufficient to cause immediate thermal killing. The affected propagules are impaired and inferior compared to untreated ones. Consequently, they become weakened and more vulnerable to antagonistic soil mocroorganisms, which are less effective against intact, nonweakened propagules. This may ultimately lead to a reduction in inoculum density and disease incidence. Thus, weakening leads to biological control of the pathogen and is reflected in a decline of the pathogen population (Freeman and Katan, 1988). A solarization-triggered weakening effect has been demonstrated in a variety of pathogens, including *F. oxysporum* f. sp. *niveum* (Freeman and Katan, 1988), *F. oxysporum* f. sp *melonis* and *F. oxysporum* f. sp *radicis-lycopersici* (Eshel *et al.*, 2000), *Sclerotium rolfsii* (Eshel *et al.*, 2000; Lifshitz *et al.*, 1983), *Sclerotinia sclerotiorum* (Philips, 1990), and others.

Flow-cytometric, physiological, and microscopic studies on the viability of sublethally heated *Fusarium* conidia showed that, although they were seemingly unaffected when examined shortly after heating, their population was reduced later on, even under axenic conditions, suggesting delayed mortality (Assaraf *et al.*, 2002). This study again suggests that assessing the levels of pathogen populations shortly after exposure to a control agent does not necessarily reflect the full potential of the weakening phenomenon induced by sublethal treatment in pathogen and disease control. The phenomenon of delayed mortality caused by sublethal heating, its possible connection to programmed cell death, and the implications regarding self-deterioration of the weakened propagules and pathogen control need to be further studied.

In certain cases, weakening is reflected in microscopic changes in the propagule. For example, exposing *Sclerotium rolfsii* sclerotia to sublethal heating under controlled conditions increased the frequency of surface cracks on the sclerotia. This was accompanied by an increase in the concentrations of bacteria in or around those cracks and in the amount of ^{14}C-labeled water-soluble organic compounds that leaked from the sclerotia (Lifshitz *et al.*, 1983).

Studies have frequently shown that solarized soils become suppressive, namely, less receptive to pathogens. This can be regarded as an example of induced soil suppressiveness (Kassaby *et al.*, 1985; Greenberger *et al.*, 1987; Freeman *et al.*, 1990). In solarized and subsequently inoculated soil, the incidences of disease caused by *Fusarium* and *Sclerotium rolfsii* were lower than in untreated infested soil, the population of lytic microorganisms was higher, and suppression of chlamydospore formation was frequently observed (Greenberger *et al.*, 1987). An additional mechanism might be partial or complete nullification of fungistasis in the absence of the host, thus exposing the vulnerable germinating propagules to the antagonistic action of the soil biota.

Various studies have shown stimulation of beneficial microorganisms (e.g., biocontrol agents and plant-growth promoters) in solarized soils. These include microorganisms such as *Trichoderma* spp., fluorescent pseudomonads, *Bacillus* spp., *Gliocladium*, *Talaromyces*, and others (Stapleton and DeVay, 1984; Gamliel and Katan, 1991; Tjamos *et al.*, 1991; Stevens *et al.*, 2003). For example, populations of *Talaromyces flavus*, a thermotolerant antagonist of *V. dahliae*, increased in solarized soils (Tjamos *et al.*, 1991). Soil solarization increased the rate of infection of juveniles of the nematode *Meloidogyne javanica* by the bacterial antagonist *Pasteuria penetrans* for at least 10 months (Walker and Wachtel, 1988). The beneficial microbial shift induced by solarization might appear because thermotolerant saprophytic organisms survive, at least partially, under the mild heating of solarization, because of rapid colonization of the root zone by the surviving microorganisms, or for other unknown reasons. Cook and Baker (1983) indicated that saprophytic microorganisms, compared to parasites, tend to have a wider temperature range over which growth is possible. Frequently, but not always, soil solarization seems to create a soil environment that favors saprobes. It should be noted that in a typical agricultural soil, plant pathogens are only a very small proportion of the total flora; chances are good that certain antagonistic species will survive the mild heating involved in the solarization process.

The stimulation of fluorescent pseudomonads in the rhizosphere of tomato plants, but not in the bulk soil, was connected with changes in the composition of root exudates from plants growing in solarized soil, i.e., increased levels of amino acids and amino compounds (Gamliel and Katan, 1992). It was concluded that the rapid establishment of fluorescent pseudomonads in the rhizosphere of plants in solarized soils is caused by the improved capacity of the bacteria to compete for exudates. These exudates also enhance chemotaxis of the beneficial bacteria toward the roots and affect the balance between various groups of microorganisms in the soil. The signals in solarized soils that trigger these changes in the root exudates are unknown. Pioneer colonists, which rapidly respond and colonize, have a better chance of occupying the soil niches created by the mild heating than do pathogens.

Many studies have examined the effect of soil solarization on microbial activity by quantifying populations of various groups of soil organisms using appropriate culture media. In general, these studies found that microbial activities are reduced to various extents during solarization but resume later, either gradually or rapidly, depending on various factors. In many but not all cases, these results corresponded with microbial population counts.

In recent years, molecular tools such as polymerase chain reaction combined with denaturing gradient gel electrophoresis (DGGE), terminal restriction fragment length polymorphism (T-RFLP), and others have been used to study shifts in soil community structure resulting from solarization, as well as microbial diversity and changes in the genetic structure of soil microbial communities. A marked temporally induced change in the genetic structure of indigenous soil bacterial communities was observed in solarized soil, as evidenced by the DGGE patterns of bacteria, β-protobacteria, actinobacteria

and, to a lesser extent, α-protobacteria (Gelsemino and Cacco, 2006). T-RFLP analyses of extracted soil deoxyribonucleic acid (DNA) revealed significant shifts in fungal community composition following soil solarization, which was sustained in both rice-cropping sites studied (Culman *et al.*, 2006). In another study using DGGE analysis, it was concluded that, in general, soil solarization tends to reduce the richness of bacteria and fungi (Bonanomi *et al.*, 2008). However, the population of fluorescent pseudomonads emerged as the most important factor in crop productivity.

Soil solarization might indirectly affect disease via an effect on host–plant resistance to pathogens. This is not surprising as there are studies that demonstrate physiological – including hormonal – changes in plants growing in solarized soils (Gruenzweig *et al.*, 1993, 2000). In those soils, plant growth is frequently increased. Mineral nutrient levels are also increased, as detailed below, and have the potential to affect host–plant resistance to pathogens. Soil solarization has been shown to reduce some foliar diseases despite the fact that only the roots are in contact with the solarized soil. Stevens *et al.* (1992) and Levy *et al.* (2004) found that reduction of foliar diseases in solarized soil is connected with induced resistance. Because only the roots are exposed to the solarized soil, signals may move upward in the plant, causing physiological changes (Gruenzweig *et al.*, 1993). Solarization frequently stimulates the activity of rhizobacteria, such as fluorescent pseudomonads and *Bacillus* (Stapleton and DeVay, 1984; Gamliel and Katan, 1991; Stevens *et al.*, 2003), which are potential inducers of host–plant resistance to pathogens.

Increased Growth Response of Plants in Solarized Soils

Improved plant growth and a consequent increase in yield are expected to occur when soilborne pests are controlled by any method of soil disinfestation, as has been shown in many studies. However, less expected is the phenomenon of plant-growth improvement by disinfestation of soils in the absence of major visible disease symptoms, but not ruling out minor root pathogens such as *Pythium*. The phenomenon of increased growth response (IGR) was documented in the early days of soil disinfestation and has been validated with all soil-disinfestation methods, including solarization (Wilhelm, 1965; Cook and Baker, 1983; Cook *et al.*, 1987; Chen *et al.*, 1991; Gamliel and Katan, 1991; Gruenzweig *et al.*, 1993, 1999). The increases in plant growth by soil disinfestation ranges from a few to several hundred percent. A thorough historical review of the IGR since the early days of soil disinfestation in Europe at the end of the nineteenth century was described by Wilhelm (1965). Different mechanisms have been suggested to explain this IGR in disinfested soils. These might be connected with either enhancement of potential beneficial agents, for example, beneficial microorganisms, improved mineral nutrition, or the elimination of a biotic harmful agents, including minor pathogens. The ubiquitous root pathogen *Pythium* is such a potential harmful agent that the elimination of which, by soil disinfestation, has been associated with an IGR. This was frequently reported among various crops including strawberry and cauliflower (Wilhelm, 1965), wheat (Cook *et al.*, 1987), and *Gypsophila* (Gamliel *et al.*, 1993), among others. Wilhelm (1965) considered the control of injurious soilborne organisms, for example, *Pythium ultimum*, as a more important factor in plant growth promotion than improving mineral nutrition. The significant role of *Pythium* in plant-growth suppression, and the improvement of plant growth by fumigation or solarizaiton was demonstrated for wheat (Cook *et al.*, 1987). It can be assumed that in various cropping systems different mechanisms might be responsible for the IGR phenomenon. IGR is also connected with a basic question, the definition of plant health, which is beyond disease control.

Soil disinfestation can be also used as a tool for determining the role of certain microorganisms in plant growth suppression (Cook *et al.*, 1987). In another study, the level of soluble organic substances, i.e., humic substances, was higher in the solarized soil. These soluble substances increased the growth of corn plants as well as populations of fluorescent pseudomonads, indicating an additional potential mechanism for improved plant growth (Chen *et al.*, 2000). In another study (Gruenzweig *et al.*, 1993), plant improvement was recorded in shoots of tomato seedlings and significantly higher levels of chlorophyll and protein contents were detected in plants from solarized soil, as compared to those from control soil.

The IGR has very important economic implications, which should be taken into account when considering the use of solarization.

Integrated Management Aspects

The management of soilborne pathogens cannot be based on a single measure, even a highly effective one. Moreover, it has to consider all sources of inoculum, not the soilborne sources only, and should manage them before, at and after planting. Thus, it has to be holistic. With regard to dependency on a single control measure, the methyl bromide (MB) crisis has taught one a painful lesson that must not be repeated.

The concepts of disease control have evolved over the years. In the early days, the goal was to eradicate the pathogens mainly using drastic chemicals. Only later it was realized that, in addition to the pathogen, there are other components in disease development, namely, the host and the biotic and abiotic components of the environment, which can be manipulated to suppress disease. The integrated pest management (IPM) approach became a major pillar in disease management. Consequently, the term 'disease management' replaced the term 'disease control.' The holistic IPM concept gathers all of these elements under one 'roof.' An appropriate IPM program can achieve better control with minimal use of pesticides and environmental hazards, a broader spectrum of control, and even a long-term effect. The diversity of approaches reduces the risks involved when a cropping system depends on a single control method. Combining and alternating methods of control are at the heart of IPM. The following issues should be considered when developing IPM programs for soil disinfestation and specifically for soil solarization (Gamliel and Katan, 2009).

- All pests of the crop, with an emphasis on the major ones, need to be taken into account.

- The IPM program should be in harmony with the cropping system.
- In combining methods of control, priority should be given to nonchemical methods.
- Emphasis should be placed on reducing pesticide usage, not necessarily with the aim of eliminating it entirely.
- Environmental, economic, legal, and social considerations need to be taken into account.
- When possible, decision-making tools should be used.

Combining solarization with other methods of control should be considered from two different angles: as a way of improving solarization; and as a way of improving the other method(s). For example, from the latter point of view, a suitable combination of solarization (or any nonchemical method) with a reduced dosage of pesticide makes the pesticide less harmful (and more acceptable), without reducing control effectiveness, and may even increase its effectiveness. McGovern and McSorley (1997) emphasized the potential necessity of combining solarization with other pest-management practices to ensure acceptable reduction of difficult-to-control pests, especially in suboptimal climates. When two control measures are applied together, the resultant effect on the target pest may be antagonistic, additive, or synergistic. For example, a synergistic effect has been obtained from combinations of soil solarization and biocontrol agents (Ristaino *et al.*, 1991; Sivan and Chet, 1993). The sequence of application of the combined methods is also important (Eshel *et al.*, 2000).

Combining Soil Solarization with Other Control Methods

The concept of combining solarization with other control methods emerged from the need to make use of the advantages of each method while overcoming their specific limitations. Since the beginning of the MB phase-out in 1992, the adoption of solarization and its combination with chemicals have been recognized as feasible and effective strategies. Combining solarization with fumigants and pesticides improves pest control and broadens the spectrum of affected pests. The increased control effect also reduces the required dose of the pesticide. In addition, the combination of solarization with a low rate of an appropriate pesticide may provide the benefit of wider safety margins for ensuring an effective treatment, which is a requirement for commercial users. Soil solarization may also enhance or delay the rate of pesticide dissipation from soil, thus giving the farmer an additional tool to better manage the sequence of soil treatments and crop-management practices.

The combination of organic amendments (organic material, animal manure, compost, and plant residues) with soil solarization can further improve pest control (Gamliel and Stapleton, 1993; Klein *et al.*, 2011). The term 'biofumigation' is often used to describe the incorporation of organic amendments, reflecting the mode of action of active volatile compounds generated by the decomposing biomass in the soil. This is not actually the case, however, as many different chemical and biological mechanisms are involved with organic amendments beyond active volatile compounds. These processes occur during the decomposition of organic material and act directly and indirectly on pathogen survival. Moreover, organic amendments may result in the evolution of 'soil suppressiveness,' i.e., low disease incidence and severity in the presence of a virulent pathogen and a susceptible host. It is regarded as a general soil suppressiveness (Weller, 2012), not being pathogen-specific and demonstrated with various crop residues (Klein *et al.*, 2012). The adoption of organic amendments combined with solarization as a disease-managing approach has been extended to a broad-spectrum of cropping systems. Improvements are continuously being made in providing consistent and reproducible results, and in formulating organic materials as commercial products (as with chemical pesticides) for maximal efficacy and consistency.

Another attractive approach to improving solarization is to combine it with beneficial organisms that can improve plant production both directly and indirectly. The survival and even increase in populations of natural thermotolerant antagonists are common in solarized soils. The application of selected antagonists that can survive solarization is of special interest, for both pre- and postsolarization application of biocontrol agents. Modifying soil conditions through solarization can improve reproducibility and the biocontrol performance of the appropriate organism.

The goal of combining solarization with other agents is to provide additional tools for disease management and enhancement of crop production. To place these tools in the growers' hands, the whole approach (solarization application, commercial formulation of the combined agent (organic material and beneficial organism), as well as its application technology) has to be feasible and economical for commercial implementation.

Technological Aspects

Huge advances in soil solarization as well as the innovations in intensive agriculture are attributed, among other things, to the development and adoption of plastic materials in various forms for different applications. The most common plastic film used for solarization is transparent low-density polyethylene. However, even the simple film must have some important properties to ensure that the plastic holds for several weeks, which might be too long under certain open-field conditions of intensive photodeterioration and wind forces. This is also the major application challenge of continuous solarization relative to soil fumigation: in the latter, the plastic only needs to hold for a few days. For example, the deterioration of transparent plastic is rapid during the hot season, under intense solar irradiation. Therefore, additional characteristics are needed to provide a better film for soil solarization. Indeed, certain additives are incorporated into the film for soil solarization to modify or enhance some specific property, such as irradiation transmittance, protection from ultraviolet (UV) degradation, and increased film strength. Protection of plastic sheets for solarization is done by amending them with various UV-light stabilizers. Water droplets condense rapidly on the under-surface of plastic mulch. The condensed water interferes with the transmittance of irradiation and may reduce the extent of soil heating. Addition of wetting agents causes water droplets to coalesce

and the runoff is returned to the soil. This keeps the film more transparent for maximum sunlight penetration. Antifog (or antidrip) agents act like surfactants, such that the moisture forms a continuous, transparent layer on the undersurface of the film rather than forming droplets that create haze and reduce light transmission.

The thickness of the film has no major effect on soil heating, hence the cost of the film and its strength with respect to the application technology dictate the thickness of the film to be used. In practice, solarization can be applied using a thin sheet of 25-μm thickness.

Applying soil solarization is a relatively simple procedure. It requires soil preparation, which includes removing plant residue from the soil surface and leveling the surface of soil clods by hand or machine. The soil has to be smoothened and irrigated down to a depth of 50 cm before the plastic film is laid, because, as a rule, organisms are more sensitive to heating under moist versus dry conditions (Shlevin *et al.*, 2003). Plastic is normally laid in the field for 4–6 weeks during the appropriate climate, i.e., with maximal ambient temperatures and solar irradiation.

Soil mulching for solarization can be performed manually with relatively small plots, or with special mulching machinery, which is preferred for large fields. In the former, the films are laid manually and anchored by narrow sand windrows. The soil in the windrows can be placed inside clear plastic bags, enabling its solarization as well, and leaving no soil unsolarized.

In mechanized solarization, the plastic film is unrolled and a trench is opened to bury the edge. Soil anchoring is then performed by covering with soil using a roller or disc. Broadcast application aims to cover the entire plot to be solarized. The tarp-laying machine unrolls a plastic strip (2–4 m width) with one edge of the sheet anchored to the soil in a trench on one side of the plot (as described for strip application) and the other edge of the film overlapping and connected by glue or welded to the adjacent plastic sheet laid at the previous pass. An alternative system that involves welding the polyethylene and fusing the sheets together was developed in Israel (Grinstein and Hetzroni, 1991). This technology is now the major method used for broadcast solarization as well as other fumigation applications in Israel.

A different approach to soil solarization is the application of sprayable polymers, which can offer a feasible and cost-effective alternative to the commonly used polyethylene sheet. This approach is based on spraying a water-based formulation of plastic polymer that forms a membrane film on the soil surface. The uniformity and porosity of the membrane depends on the type and formulation of the polymer. In fact, the use of liquid formulations for spray mulch was suggested even before solarization was developed (Bochow, 1989), but these were oil-based. Later, the development of latex-based mulches offered more feasible options for application (Audette and Pole, 1987). In Israel, a sprayable polymer product, Ecotex, was developed along with the technology to apply it economically on soil for a variety of purposes (Gamliel and Becker, 1996). Soil coating with the black polymer formulation using this technology resulted in a membrane film that could raise soil temperatures close to solarization levels (Gamliel and Katan, 2009). The soil-heating process is faster with sprayable mulch than with plastic film, but the soil also cools down to lower temperatures at night. In another study, a water-based varnish made of a biodegradable polysaccharide mixture containing biodegradable plasticizers was suggested. However, its practical use was not demonstrated. Obviously, this approach is promising, especially for open-field conditions, but its adoption requires further improvements.

Solarization in the open field has the advantage of direct exposure to solar irradiation with no interference. However, technical difficulties, such as improper and poorly timed mulch application, maintaining film integrity under harsh conditions for several weeks, and film removal, cause difficulties for commercial implementation of solarization under open-field conditions. Development of innovations in the application of solarization should focus on better mulching technologies, including improved films and polymers, and specifically photodegradable films. Additional development should also aim at plastic removal and disposal. Meeting these challenges, together with the adoption of strategies for IPM, will certainly promote the extended use of solarization for large-scale application in the open field.

Solar Heating of Soil and Pathogen Response to Heating: Principles and Modeling

Reduction of pathogen populations during the solarization process is a key (but not the only) factor for disease reduction. Thermal-killing of the pathogen (in addition to other mechanisms) is responsible for this reduction and is connected with both soil temperature and the pathogen's sensitivity to that temperature. These two topics will be discussed below.

Soil Heating during Solarization

The patterns of solar heating of soil, with or without plastic, are characteristic. Knowing the factors involved in heating enables optimizing the solarization process.

A variety of models for predicting temperatures of solarized soils under various climatic conditions have been developed and validated. The first models were developed for arid conditions (Mahrer, 1979; Mahrer and Shilo, 2012). Simplified models (Cenis, 1989), and those suitable for more humid areas (Wu *et al.*, 1996), were also developed. A 1-cm^2 area outside the earth's atmosphere and parallel to its surface receives 2 cal cm^{-2} min^{-1} (solar constant) of energy in the form of solar radiation; but only about half of that reaches the ground. The energy is lost from the soil in the form of long-wave radiation (depending on water vapor and clouds) through conduction, convection, and water evaporation; the latter being a very important factor in wet soils. The heat that penetrates the soil surface is stored in the soil and, at night, when the thermal gradient is reversed, it is lost again due to a cyclic reversal in the direction of heat flow. In principle, because the rate of heat flow through the soil depends on the soil's thermal properties and the temperature gradient to which it is subjected, the temperature regime at a given depth can be predicted using equations for calculating an energy

budget that take into account all factors involved in soil heating, including plastic properties.

Mahrer (1979) developed a one-dimensional numerical model for such predictions. Indeed, the predicted temperatures in mulched soils were very much similar to the observed ones, the magnitude of error being within the range of 0.6–1.2 °C. Models describing spatial soil temperature regimes in solarized soils and closed greenhouses have also been developed.

Response of Pathogens to Elevated Temperature

The thermal death rate of a population of an organism depends on both the temperature and exposure time, which are inversely related. Various methods have been developed to evaluate thermal effects on organisms and to quantify the time–temperature relationships and the organisms' inherent heat sensitivity. Certain thermal death curves have an exponential nature, which indicates that a constant fraction of the population is killed per unit of time. In some cases, a linear relationship was revealed by plotting logarithms of time required to kill 90% of populations of various pathogenic fungi against temperature (Pullman *et al.*, 1981).

Modeling pathogen control by solarization is usually based on studies of thermal inactivation of pathogens, using data collected under constant elevated temperatures. Based on chemical reaction kinetics at constant temperatures, an exponential inactivation relationship is typically expected. Traditionally, thermal inactivation of microorganisms is considered a first-order reaction, characterized by a logarithmic change in the organism's population with time. Studies on thermal inactivation under fluctuating temperatures, such as those naturally prevailing in the field, are much more complicated because the partial effects of varying temperatures on pathogens are difficult to weigh, and they require numerical integration to account for their complexity (Shlevin *et al.*, 2003). There are other approaches to simulating and modeling pathogen control by solarization, for example, by plotting the level of mortality versus accumulated hours above a certain temperature, i.e., degree–hours (DH). Shlevin *et al.* (2003) developed a model describing the process of pathogen control with time under structural (dry) solarization. In another study on modeling regular (wet) soil solarization, the common DH approach for predicting the rate of heat inactivation was further improved by giving different weights to the different temperatures, thus refining the correlation between temperature data and pathogen survival from $R^2 = 0.324$ to $R^2 = 0.86$.

Soil Solarization in Various Cropping Systems

Since 1976, research into soil solarization has expanded in many countries. Although it is a climate-dependent method, it has been introduced in countries with different climates, soils, and cropping systems. Furthermore, soil solarization has been embraced and adapted for various production systems characterized by different economic structures, agricultural traditions, and farmer attitudes. Therefore, it is not surprising that solarization has developed in different ways, with modifications producing different solutions for specific problems and needs. Nevertheless, research, development, and implementation of soil solarization share common features in the various cropping systems with those in which it was developed (Katan and DeVay, 1991). The success of soil solarization as a practical approach led to the evaluation of solarization in other marginal and cool climates, inside structures or as an outdoor application, as well as in humid areas where cloudy conditions and rain are common during the solarization period (Walters and Pinkerton, 2012). Below are examples from some of those countries.

In Europe, especially in the northern regions, as well as in Japan, the approach of solarizing the soil inside closed greenhouses was developed (Garibaldi and Gullino, 1991; Horiuchi, 1984). This results in further elevation of soil temperatures (and more effective disease and weed control) compared with solarized soils in the open field due to the double plastic layers from both closing the greenhouse and mulching the soil. Greece was one of the first countries to realize the potential of soil solarization, especially in plastic houses and glasshouses, and to a lesser extent with field crops, for a variety of vegetables and flower crops, and perennial crops such as artichoke and olive (Tjamos *et al.*, 2012). They found that many fungal pathogens, as well as the pathogenic bacterium *C. michiganensis* subsp. *michiganensis*, were well controlled. In India, soil-solarization studies have been carried out in many regions, including arid ones, with an emphasis on combining solarization with local organic amendments (Lodha and Mawar, 2012). Soil solarization, especially when combined with low dosages of fumigants, is applied on a large scale in Turkey. In Israel, soil solarization is successfully used with a variety of crops, in both open field and greenhouses, with an emphasis on combining it with other measures (Gamliel and Ausher, 2012). Soil solarization is well-adapted to organic farming and home gardens in many countries.

Technology Transfer and Adoption of Soil Solarization

Technology development in agriculture relies on three components: technology generation, diffusion, and adoption. Successful technology transfer depends primarily, but by no means solely, on a long-term collaboration between research, agricultural extension, and farmers. Advancing and monitoring adoption at the growers' level is an extension task. The development of soil solarization in Israel was first evaluated by farmers and extension specialists in the Jordan valley in Israel where, for the first time, they came across the possible disinfestation effect of transparent plastic mulch during one hot summer (Grinstein and Ausher, 1991). This initial observation was further developed by a multidisciplinary team of researchers and agricultural extension specialists. Therefore, when soil solarization evolved into an applicable technology at the growers' level, it was already well received by both extension workers and growers. Still, for the first 20 years after its release, soil solarization remained a niche treatment, and its wide-scale adoption was slow. This was mainly due to bottlenecks in four major areas: application problems, low efficacy with specific soilborne pests, the cost factor, and the human factor. A lack of awareness of the particular benefits of solarization, as well as a lack of technical information, were also identified as factors impeding large-scale utilization of the method.

From a technology-diffusion perspective, solarization can be regarded as a component of IPM and biological control systems. These systems and techniques are complex and often more expensive than the equivalent chemical control methods. Moreover, solarization was only backed by public research and development organizations, with little or no involvement of the private sector in the promotion or marketing of the whole technological package. Therefore, the dissemination of soil solarization relied mainly on intensive, but limited to, one-to-one advisory contact between researchers and farmers. Although individual extension specialists were involved in the development of solarization right from the start, the method was not yet fully adopted by the Ministry of Agriculture as a system-wide policy at that time, except for the control of pink root rot in onion and broomrape.

Today the use of soil solarization is on the rise. For the most part, this is due to specific crop systems and specific regions pioneering the adoption of solarization in practice, mainly in combination with other methods. Moreover, the phase-out of MB and the fact that many chemical alternatives to MB have deleterious environmental effects have recently boosted the use of solarization. Successful results of solarization used in combination with fumigants such as 1,3-D, 1,3-D/Pic, metham sodium, and dazomet have been reported from different countries and for different crops and cropping systems for many years. The greatest advantage of these combinations is up to 50% reduction in fumigant dosage rates, which minimizes the impact of fumigants on the environment and often lowers costs. From an extension-advisory perspective, the applicability of these formulas has been demonstrated in the field for the major crop/pathogen combinations to ensure its rapid dissemination and adoption.

Other Uses of Solarization

Soil solarization was originally developed as a preplant soil disinfestation tool for annual crops. However, its application and uses have expanded since its early days, and continue to expand to various areas and fields of interest. These unusual uses are based on solar heating. Following are some examples:

1. Soil solarization in existing orchards to control soilborne pathogens (which is impossible to achieve with fumigants) is a deviation from the classical preplant application. It was pioneered by Ashworth and Gaona (1982) for the control of Verticillium wilt in pistachio orchards. The success of this approach depends on a variety of factors, such as the extent of damage inflicted on the trees during solarization and the effectiveness of solarization in shaded areas. Postplant solarization also reduced the incidence of Verticillium wilt in olives (Tjamos *et al.*, 1991) and *Rosellinia necatrix* in apple (Freeman *et al.*, 1990). The recovery of infected trees following the application of solarization is a highly desirable goal.
2. Solarization can be used as a sanitation tool, for example, for disinfestation of tomato supports that transmit *Didymella lycopersici* (Besri, 1983), structural solarization of closed greenhouses (Shlevin *et al.*, 2003), disinfestation in container nursery production (Stapleton and Faddoul, 2012), disinfestation of reused polysterene trays and soil piles (Nico *et al.*, 2003), among other uses.
3. Soil solarization is not practical for rice production. Nevertheless, solarization of rice nursery soils for the production of healthy seedlings is a simple, low-cost, nonchemical soil treatment for the suppression of pathogens in flooded soils. Thus, when rice seedlings were produced in solarized nursery soil, the health of the mature rice plants was significantly improved (Culman *et al.*, 2006; Gamliel and Katan, 2012).
4. Contribution to human health: soil solarization is effective at reducing the incidence of corn ear rots and consequently, produces mycotoxin-free crops and increases the productivity and quality of the corn grains (Yasmin and Ghaffar, 2007). Similarly, it reduced the colonization of peanut pods by *Aspergillus niger*, which is also a source of mycotoxin production (Grinstein *et al.*, 1979).

   Human infection with foodborne pathogens has occasionally been linked to field-soil contamination with fecal pathogenic bacteria, which can be brought to agricultural fields by animal manure. Soil solarization eliminated a population of *Escherichia coli* within 4 weeks of treatment, with no influence on the total direct and viable counts of other bacteria in the soil (Wu *et al.*, 2009). In another study, solarization of soil amended with raw chicken manure resulted in reduced counts of *Staphylococcus aureus*, *Clostridium perfringens*, and fecal coliform bacteria (Barbour *et al.*, 2002). These findings indicate that soil solarization can be useful for biosafety and the control of soil contamination by human pathogens via immature compost or animal manure.
5. Soil solarization for home gardens and landscapes.
6. Solarization of plant-growth media and potting mixes, some of which are difficult to fumigate (Stapleton and Faddoul, 2012).

The use of 'old' (i.e., previously used) polyethylene provides for extremely inexpensive solarization. Avissar *et al.* (1986) found that such used polyethylene can be effective for soil heating.

Concluding Remarks

The initial goal of soil solarization was quite modest: to explore the possibility of effectively using solar heating of the soil for the control of Verticillium wilt in two crops in a specific hot region in Israel. However, its rapid development led to its success in controlling a wide-spectrum of pests, well beyond its initially intended scope. Pest control by solarization has developed from the primary goal of simply killing the pathogen and reducing disease incidence, to the concept of integrating additional objectives, such as economic aspects as well as minimal disturbance of the biotic and abiotic components of the environment. Thorough studies on the mechanisms involved, with emphasis on the biotic ones, were essential for achieving the above goals. The philosophy of IPM is responsible for the evolution of other aspects of soil solarization. Other global changes, such as the phase-out of soil fumigants – mainly MB – further boosted the adoption of solarization in soil-disinfestation programs.

The adoption and implementation of solarization by farmers can be achieved by developing a feasible, cost-effective application technology. The application of solarization, namely, tarping a plastic sheet over moist soil and allowing the sun to do the rest, seems to be an easy way. Nevertheless, many aspects of its application, including soil preparation, tarping, and plastics technology are involved in achieving successful solarization. The need for application methodologies suited to each specific solarization niche, for example, open field, closed greenhouse, and strip solarization, has led to specialized research and development.

The success of soil solarization has led to its implementation in other marginal areas. Solarization has now been shown to be effective in northern regions as well, such as in the Pacific Northwest of the USA. Similarly, solarization has been introduced into humid areas where cloudy weather and rain are common during the summer. The significant role of soil solarization as an element in integrated control should be further expanded. Further developments of predictive meteorological tools and models, as well as other related topics, are essential in providing a more solid background for further development and implementation of solarization. The development of soil solarization clearly demonstrates that even a climate-dependent management method can be harnessed, for certain situations, if it is properly introduced and its expansion is carefully and gradually carried out.

In a dynamic and continuously changing agricultural, social, political, and economic global climate, it is extremely difficult to predict future measures for crop protection. Nevertheless, it is our duty to closely follow and respond to those changes, to improve our research techniques, and to continuously prepare alternative management methods, well ahead of time, rather than only when a solution for a crisis is urgently needed. The IPM concept, which reflects reality and a practical approach, should become more of a central pillar in soil disinfestation than it is today, as it is in solarization. The IPM concept has the flexibility required to better adapt to our agricultural systems, with expected and unexpected changes.

UTR	Untranslated region

Glossary

amiRNA An ~21 nucleotide small RNAs generated from the natural miRNA precursors by replacing the natural miRNA sequence in the precursor.
Gene silencing The mechanism by which the functions of one or many genes are inhibited or reduced either before (transcriptional gene silencing, TGS) and or after transcription (post-transcriptional silencing, PTGS).
Guide strand siRNA One of the two strands of duplex siRNA which is complementary to the target messenger RNA.
Micro RNA (miRNAs) Small RNAs of ~21 nucleotide length generated by the processing of self complementary precursor transcript.
Post-transcriptional gene silencing (PTGS) PTGS involves the processes which leads to the sequence specific cleavage of target mRNA or inhibition of its translation.
Resistance It is a state in which a plant shows no or mild or delayed symptoms of virus and undetectable level of virus genome by one of the molecular detection method.
RNA-induced silencing complex (RISC) A multi-enzyme complex effecting the cleavage of the target mRNA. It contains a slicer and guide siRNA strand.
Small interfering RNA (siRNA) A ~21 nucleotide duplex RNA generated from the long dsRNA substrates by the action of dicer-like proteins.
Suppressor of gene silencing A group of proteins usually encoded by the plant viruses which inhibit one or many steps of the gene silencing pathways.
Transgenic plant A plant regenerated by transforming it with a vector containing one or more foreign DNA sequences including promoter sequences.

Introduction

Both single-cell and multicellular organisms control their physiological processes through their genetic material either directly or indirectly by their products, such as various types of ribonucleic acids (RNAs) and proteins in response to internal and external cues. In a multicellular eukaryotic organism, all the genes are not expressed all the time, but genetic and epigenetic factors and processes regulate them spatially and temporally. Eukaryotic organisms, including plants, have evolutionarily conserved mechanisms to evade the invasion by foreign genetic materials, such as transposons, viruses, and bacteria. One such mechanism is post-transcriptional gene silencing (PTGS), also called as RNA interference (RNAi) in animals and quelling in fungi. In PTGS, expression of a gene (endogenous, transgene, or foreign genetic material) is regulated after it is transcribed into a messenger RNA (mRNA). PTGS plays a pivotal role in the development of an organism and in the protection from invading foreign genetic material, including viruses. It acts in a sequence-specific manner by cleaving and by translational suppression of mRNA. PTGS is triggered by the formation of a hairpin-like structure of a mRNA or a double-stranded RNA (dsRNA). RNA hairpin-like structures are thought to be formed by bidirectional transcription of overlapping gene regions, aberrant transcription from inverted repeat regions, and dsRNA genomes of viruses or replication intermediates of viruses.

It is believed that the first report of RNA silencing might have been by Wingard in 1928, in which initially infected leaves with tobacco ringspot virus appeared necrotic and diseased. However, the upper leaves were immune to the virus, asymptomatic and resistant to secondary infection (Baulcombe, 2004; Wingard, 1928). At that time the mechanism of recovery and specificity of resistance to secondary infection was unknown. With the report of a new concept of pathogen-derived resistance (PDR) (Sanford and Johnston, 1985), it was shown that virus-derived sequences, for example, coat protein (CP) gene, conferred resistance to the same or related viruses (Powell-Abel *et al.*, 1986). Many of the initial studies employed pathogen-derived (CP-mediated) resistance strategy (Beachy, 1997) to develop virus resistance and used sense or antisense gene constructs to impart virus resistance in transgenic plants (Yadav

 doi:10.1016/B978-0-444-52512-3.00219-9

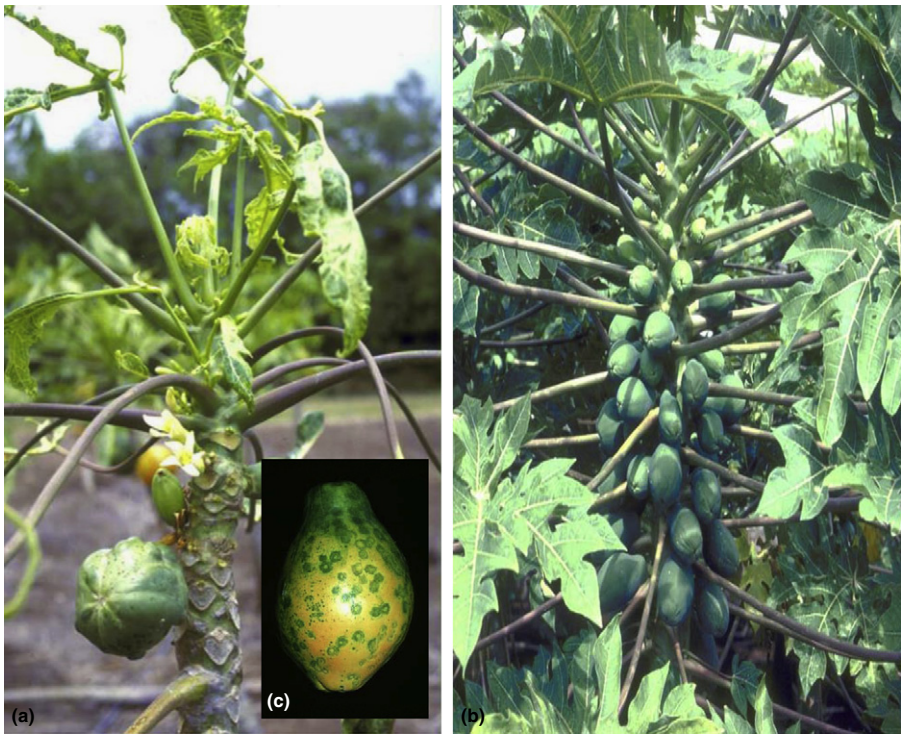

Figure 1 Transgenic papaya resistant to PRSV. (a) Non-transgenic sunrise, (b) transgenic virus-resistant Rainbow papaya (*Carica papaya* L.) in the field, and (c) ringspot symptoms on papaya fruits infected with PRSV. Courtesy of S. Ferreira.

et al., 2007). Several groups reported virus resistance using the coat protein-mediated resistance (CPMR) strategy, although it was unclear for many types of viruses whether the expression of the CP was required for inducing virus resistance, and probably many of them were using the PTGS mechanism, unknown at that time. For the sake of simplicity this article mostly review the cases where PTGS was clearly involved in the resistance; otherwise, the readers are advised to refer to the review of Yadav *et al.* (2007). For example, transgenic papaya transformed with the CP of Papaya ringspot virus (PRSV) was developed and successfully deployed in the field (**Figure 1**, Ferreira *et al.*, 2002). However, the exact mechanism of PDR was not known at that time because both protein-coding and nonprotein-coding virus sequences conferred virus resistance (Tacke *et al.*, 1996).

In the early 1990s Jorgensen's lab reported co-suppression of both the transgene and the endogenous gene when the transgene was over-expressed in petunia (Napoli *et al.*, 1990). Following this report many research groups reported that silencing of endogenous, transgene, or both genes could be achieved by over-expressing the sense or antisense copy of the gene. However, it was not until the report by Andrew Fire and Craig Mello in 1998 that RNA silencing started to receive more attention when they showed that dsRNA is much more efficient in silencing the homologous mRNA than either sense or antisense strand of a gene (Fire *et al.*, 1998; Tabara *et al.*, 1998). Subsequently, it was observed that corresponding small RNAs (of size ~ 21nt) accumulate in the silenced plants (Hamilton and Baulcombe, 1999).

Regarding plant virus resistance, as early as 1993, Lindbo *et al.* (1993) had first demonstrated RNA-mediated resistance against viruses in plants. Central to the RNA silencing mechanism are the small RNAs (Hamilton and Baulcombe, 1999). Small interfering RNAs (siRNAs) are 21–23nt long with 2-nt 3′ overhang that mediates the cleavage of the target RNA (Elbashir *et al.*, 2001a,b). The 3′ structure of the siRNAs suggested that they are the products of enzymatic cleavage and the 2nt overhang suggested features of RNase III endonuclease. There are several classes of small RNAs with diverse structures and functions (**Figure 2**).

The role of innate PTGS for the plant virus control was also suggested by the accumulation of virus-derived siRNAs in virus-infected plants and the increased susceptibility of the plants to viral infections when genes involved in PTGS were mutated (Hamilton and Baulcombe, 1999). Presence of virus-encoded suppressors of gene silencing and their functions in various steps of PTGS further supported their role in the plant virus control (Li and Ding, 2006). Very recently, an antiviral role of RNAi has been shown against mammalian viruses (Li *et al.*, 2013; Maillard *et al.*, 2013). To exploit this innate antiviral mechanism, plants were genetically modified to express virus-specific dsRNAs to trigger the PTGS system (Smith *et al.*, 2000). The gene silencing mechanism used to control viruses based on either short or long hairpin constructs involves the cleavage of dsRNA molecules into short duplex 21–26nt siRNAs (Baulcombe, 2004; Hamilton and Baulcombe, 1999) by the action of RNase III endonucleases, such as four Dicer-like proteins in *Arabidopsis thaliana* (DCL1 to 4) (Golden *et al.*, 2002; Park *et al.*, 2002). One of the strands of duplex siRNAs (guide strand) is incorporated into the multi-subunit endonuclease complex called RNA-induced silencing complex (RISC). RISC consists of a complex of

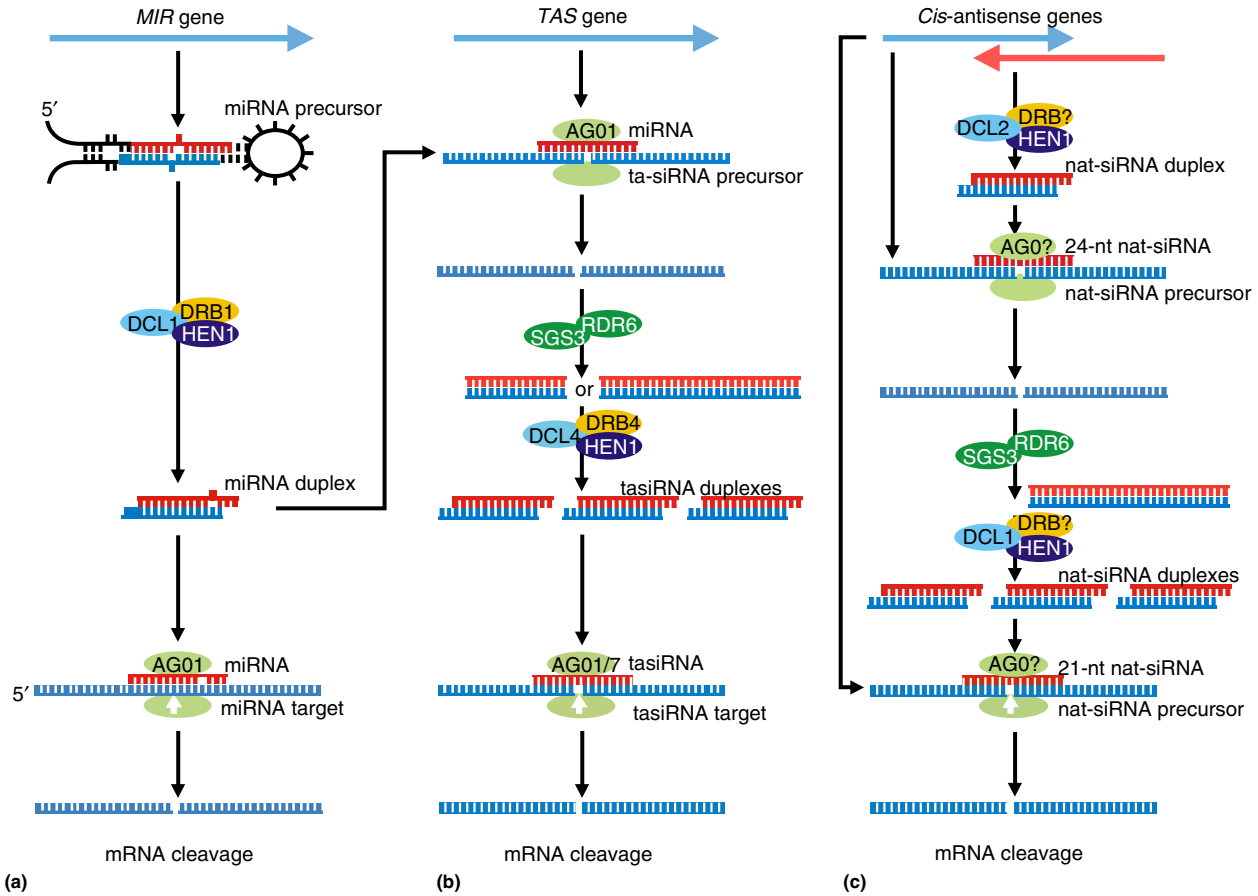

Figure 2 Diversity of small RNA pathways in plants. (a) miRNA pathway, (b) and (c) siRNA pathways. DCL1, Dicer-like protein 1; DRB1, Double-stranded RNA-binding protein 1; HEN1, Hua enhancer protein 1; AGO1, Argonaute protein 1; SGS3, Suppressor of gene silencing 3; RDR6, RNA-dependant RNA polymerase protein 6; ta-siRNA, trans-acting siRNA; nat-siRNA, Natural antisense siRNA. Adapted from Eamens, A., Wang, M.B., Smith, N.A., Waterhouse, P.M., 2008. RNA silencing in plants: Yesterday, today, and tomorrow. Plant Physiology 147, 456–468.

proteins, including one of several Argonaute proteins. There are, for example, at least 10 Argonaute proteins in *A. thaliana*. RISC mediates the sequence-specific cleavage of the target mRNA between the positions 10 and 11 of the ~21nt guide strand, by the slicer function of the Argonaute protein. Primary siRNAs (those generated by the processing of initial dsRNA triggered by the action of DCL proteins) can also bind to the target RNA, and a secondary dsRNA can be synthesized by the action of RNA-dependent RNA polymerases (RdRPs). The siRNAs generated by this mechanism are called secondary siRNAs and the phenomenon is called transitivity because secondary siRNAs can also be produced from the nucleic acid regions beyond the primary target, thus increasing the efficiency of the RNAi (Sijen *et al.*, 2001; Vaistij *et al.*, 2002). In *A. thaliana* there are at least six RdRPs. The presence of multiple paralogs of key proteins involved in PTGS in *A. thaliana*, and most probably other plants, results in diverse siRNA pathways in plants (**Figure 2**) (Eamens *et al.*, 2008; Xie *et al.*, 2004) that can be utilized for engineering virus resistance.

To enhance the production of dsRNAs in the cell to trigger a robust PTGS, plant transformation gene constructs encoding an intron-spliced RNA with a hairpin structure have been shown to be highly efficient when directed against viruses or endogenous genes rather than over-expressing either sense or antisense copy of the gene (Smith *et al.*, 2000). Since this report, hairpin RNA-mediated PTGS has been used as a method of choice to engineer virus resistance in transgenic plants (Baulcombe, 2004; Vanitharani *et al.*, 2005).

Here the authors have discussed chronologically the recent progress reports of proof of concepts and successful applications of engineered plant virus resistance by gene silencing/PTGS for DNA and RNA plant viruses, with future opportunities/prospects and challenges. Owing to space limitations, only selected studies have been reported in order to highlight the breadth of the application of gene silencing technology to control diverse plant viruses in different host plants (**Table 1**). Most of these studies used inverted or hairpin RNA to trigger PTGS, and the virus-resistant plants were characterized by the accumulation of siRNAs specific to transgenes.

Control of Plant DNA Viruses by siRNA-Mediated Gene Silencing

Members of two DNA virus families, Geminiviridae and Nanoviridae, have small, single-stranded DNA genomes in

one or more components, for example, DNA-A and DNA-B in Geminiviridae. DNA-A encodes an essential protein for DNA replication known as Rep or AC1 or C1. DNA-B encodes proteins involved in inter- and intracellular movements (King *et al.*, 2012).

Cotton Leaf Curl Virus (*Begomovirus*, Geminiviridae)

Asad *et al.* (2003) provided the first report of expressing virus-derived sense and antisense RNAs of 5′ and 3′ halves of AC1 and AC2, AC3 overlapping regions of Cotton leaf curl virus (CLCuV) in *Nicotiana tabacum* cv. Samsun without an intron separating them. Transgenic lines showed no symptoms even after 120 days of continuous exposure to viruliferous whiteflies. The presence of dsRNA and siRNAs in selected uninfected sense lines suggested that the likely mechanism of resistance was via PTGS (Asad *et al.*, 2003).

African Cassava Mosaic Virus (*Begomovirus*, Geminiviridae)

Wild type and modified versions of full-length AC1 sense RNA of African cassava mosaic virus (ACMV) were expressed in cassava (*Manihot esculenta* Crantz). High levels of resistance were obtained to both homologous and two heterologous begomoviruses viz., East African cassava mosaic Cameroon virus (EACMCV) and Sri Lankan cassava mosaic virus (SLCMV). The presence of transgene-specific siRNAs suggested that the resistance was through PTGS (Chellappan *et al.*, 2004). Some of the transgenic cassava lines were immune to ACMV and several other geminiviruses infecting cassava (Chellappan *et al.*, 2004). ACMV resistance was also obtained by targeting both the noncoding common region of DNA-A that contains bidirectional promoters (Vanderschuren *et al.*, 2007) and the coding region of partial AC1 gene (Vanderschuren *et al.*, 2009). The authors observed a recovery phenotype in the transgenic cassava lines and, in leaf disc assays, a decrease of more than 90% in virus accumulation of single- or double-stranded DNA forms.

Tomato Yellow Leaf Curl Virus (*Begomovirus*, Geminiviridae)

In a transient virus protection assay, the hairpin construct that contains conserved noncoding sequences of four strains of Tomato yellow leaf curl virus (TYLCV) conferred resistance to the challenge by these viruses. Stable resistance with immunity to TYLCV in tomato was reported using an intronic hairpin construct targeting the 3′end of the C1 gene (Fuentes *et al.*, 2006). This is the first report of use of an 'intronic' hairpin RNA construct for resistance to a plant DNA virus. Similarly, in a transient assay using *Nicotiana benthamiana* and tomato expressing conserved noncoding sequences from several strains of TYLCV, an effective resistance was obtained upon virus challenge either by agroinfiltration or by whitefly transmission (Abhary *et al.*, 2006). Similarly, the V1 gene, which encodes the CP, was used to develop resistance to TYLCV in both transient assays (*N. benthamiana*) and in transgenic tomato plants expressing an intronic hairpin construct targeting V1 RNA (Zrachya *et al.*, 2007). The role of PTGS was also hypothesized in a previous study involving transgenic tomato plants that contain TYLCV intergenic region (IR), Rep, and C4 genes. When challenged by viruliferous whiteflies under field conditions, transgenic tomato plants for partial IR (81nt) and Rep genes (426nt of 5′end) showed best resistance (Yang *et al.*, 2004).

Bean Golden Mosaic Virus (*Begomovirus*, Geminiviridae)

In the case of Bean golden mosaic virus (BGMV) infecting the common bean, targeting the AC1 by intron-spliced hairpin RNA resulted in immunity in one of the transgenic lines (5.1) (Bonfim *et al.*, 2007). These transgenic lines are being evaluated in the field for release to the farmers in Brazil (Aragao and Faria, 2009). In 2011, it was approved for commercialization by the National Technical Commission on Biosafety (CTNBio) of Brazil, but it was also requested to do more multilocation field trials in the country.

Tomato Chlorotic Mottle Virus (*Begomovirus*, Geminiviridae)

An interesting feature of PTGS-mediated virus resistance in the case of DNA viruses is that the presence of virus-specific siRNAs does not seem to guarantee the resistance/protection against the virus as shown by the studies in Tomato chlorotic mottle virus (ToCMoV); similar levels of siRNAs were observed in resistant and susceptible lines of the same *N. benthamiana* line transgenic for a gene hairpin construct derived from the overlapping regions of three genes viz., AV1-AC1-AC4 (Ribeiro *et al.*, 2007).

Chickpea Chlorotic Dwarf Pakistan Virus (*Mastrevirus*, Geminiviridae)

PTGS-based resistant *N. benthamiana* plants have also been developed for the Chickpea chlorotic dwarf Pakistan virus (CpCDPKV), a member of the genus *Mastrevirus*, expressing a chimeric construct that consists of three genes of CpCDPKV (Nahid *et al.*, 2011). Transgenic plants were symptomless and flowered normally, whereas the controls showed symptoms and died at 25 days post-inoculation. The virus accumulation in transgenic versus non-transgenic plants was estimated by PCR to be between 2600 and 28 000 times less.

Banana Bunchy Top Virus (*Babuvirus*, Nanoviridae)

Transgenic bananas (*Musa sp.*) resistant to Banana bunchy top virus (BBTV) were developed by targeting the Rep gene (Elayabalan *et al.*, 2013; Shekhawat *et al.*, 2012). Transgenic banana plants expressing RNAi-BBTV rep were obtained and shown to resist infection by BBTV. The transformed plants were symptomless, and the replication of challenging BBTV almost completely suppressed.

Control of Plant RNA Viruses by siRNA-Mediated Gene Silencing

RNA viruses form a large class of plant viruses. They have either single- or double-stranded RNA genomes in one or

Figure 3 Plum pox virus-resistant transgenic plum (*Prunus* × *domestica* L.) HoneySweet plums, sweet and flavorful, are highly resistant to plum pox virus. Courtesy of USDA ARS.

several segments. In the case of single-stranded RNA viruses the genome can be of positive sense, negative sense, and in some cases ambisense (King *et al.*, 2012).

Papaya Ringspot Virus (*Potyvirus*, Potyviridae)

There are two main strains of PRSV based on host range. PRSV-P (papaya strain) infects both papaya and cucurbits, whereas Papaya ringspot virus (Watermelon strain) (PRSV-W) infects only cucurbits. Based on the concept of PDR, and by expressing the CP gene from a mild strain of PRSV, a virus-resistant transgenic papaya line (55-1) was developed (Fitch *et al.*, 1992). Transgenic line 55-1 was later used to develop two popular cultivars viz., SunUp (red flesh, homozygous for CP transgene) and Rainbow (yellow flesh, heterozygous for CP) (Manshardt, 1998). Although this was one of the early successful cases of CPMR, it was later shown to be a case of PTGS based on two observations: First, resistance was higher to PRSV isolates, which showed higher homology to the transgene; second, homozygous transgenic line showed broader resistance to different PRSV isolates with lower steady state levels of *CP* transgene mRNA compared with hemizygous transgenic papaya (Suzuki *et al.*, 2009).

Plum Pox Virus (*Potyvirus*, Potyviridae)

Plum (*Prunus* × *domestica*) trees transgenic for multicopy CP gene, with a complex integration pattern, were highly resistant to Plum pox virus (PPV) (Scorza *et al.*, 1994). The mechanism of resistance was by transgene methylation (**Figure 3**; Scorza *et al.*, 2001). In another study, a 197bp self-complementary hairpin RNA of PPV expressed under *rolC* promoter conferred systemic resistance to PPV in *N. benthamiana* but no local resistance (Pandolfini *et al.*, 2003).

Zucchini Yellow Mosaic Virus, Watermelon Mosaic Virus 2, Papaya Ringspot Virus (all *Potyvirus*, Potyviridae), and Cucumber Mosaic Virus (*Cucumovirus*, Bromoviridae)

Transgenic summer squash lines with different combinations of Cucumber mosaic virus (CMV), Zucchini yellow mosaic virus (ZYMV), and Watermelon mosaic virus 2 (WMV2) CPs (one to several copies) showed variable field resistance to these viruses. Two of the inbred transgenic lines, ZW-20 and CZW-3, which contain CP genes from ZYMV, WMV2 and CMV, of which ZYMV and WMV2 showed higher resistance, were utilized to develop commercial squash hybrids (Tricoll *et al.*, 1995). The mechanism of virus resistance is believed to be mediated by PTGS. In another study the RNAi construct that contains the self-complementary RNA of ZYMV HC-Pro gene was used to develop transgenic cucumber and melon. The level of siRNAs derived from HC-Pro transgene varied from 6% to 44% of total siRNAs and conferred resistance to ZYMV systemic infection. Resistance to WMV and PRSV was also observed in a cucumber line accumulating 44% of transgene siRNAs and higher levels of RDR1 and AGO1. This study also reported that transgene siRNAs are not uniformly distributed over the transgene but accumulated in hot spots, which may not be responsible for the resistance phenotype (Leibman *et al.*, 2011).

Barley Yellow Dwarf Virus (*Luteovirus*, Luteoviridae)

Barley plants transformed with a Barley yellow dwarf virus (BYDV)-PAV polymerase hairpin construct exhibited extreme resistance (immunity) to BYDV virus challenge. When co-challenged with Cereal yellow dwarf virus-RPV (CYDV-RPV), transgenic plants were susceptible to CYDV-RPV but were resistant to BYDV-PAV, indicating robust homologous specific resistance (Wang *et al.*, 2000).

Beet Necrotic Yellow Vein Virus (*Benyvirus*, Unassigned family)

Nicotiana benthamiana plants expressing a CP read through open reading frame resulted in plants resistant to Beet necrotic yellow vein virus (BNYVV), which was less effective in roots than in foliar tissues (Andika *et al.*, 2005). Recently, Pavli *et al.* (2010) targeted the replicase gene of BNYVV by expressing a replicase-specific dsRNA in the beet roots mediated by *Agrobacterium rhizogenes* hairy root transformation. The transgenic roots showed none to very low virus titer with delayed symptom development (Pavli *et al.*, 2010). In a related study, transgenic *N. benthamiana* lines expressing dsRNA produced from a hairpin BNYVV replicase gene and HrpZ protein (a bacterial protein, found to elicit hypersensitive response in host plant) conferred higher resistance to BNYVV than the individual genes (Pavli *et al.*, 2010).

Tobacco Mosaic Virus (*Tobamovirus*, Virgaviridae)

Tobacco mosaic virus (TMV) is the first virus against which the use of the CPMR was demonstrated (Powell-Abel *et al.*, 1986). At that time PTGS was not discovered and consequently there was no evidence that PTGS was involved, and several subsequent studies demonstrated that the CP was necessary and involved in the resistance mechanism (for more details see Beachy 1997, Yadav *et al.*, 2007). An RNAi construct of TMV coat protein and single copy of partial movement protein gene expressed in tobacco as an inverted hairpin also conferred resistance to TMV (Hu *et al.*, 2011; Yan *et al.*, 2007).

Citrus Tristeza Virus (*Closterovirus*, Closteroviridae)

p23 and 3′UTR sequences of Citrus tristeza virus (CTV) were used in the hairpin constructs and expressed in *N. benthamiana* and Alemow (*Citrus macrophylla*). Transgenic *N. benthamiana* and Alemow plants showed resistance and delayed symptoms, respectively. However, none of the transgenic Alemow plants showed durable resistance (Batuman *et al.*, 2006). In another study in *Citrus paradisi*, most of the transgenic lines transformed with various constructs derived from CTV were susceptible or partially resistant and only one line transformed with 3′end of CTV was virus resistant (Febres *et al.*, 2008). Complete resistance to graft inoculations of homologous CTV strain T36 was obtained in three transgenic lines of Mexican lime transformed with intronic hairpins that consist of untranslatable genes of three suppressors of CTV (p23, P20, and p25) and 3′UTR. Resistance to the divergent CTV strain (T318A) was partial (Soler *et al.*, 2012).

Poinsettia Mosaic Virus (*Tymovirus*, Tymoviridae)

Hairpin RNAi technology was also used in a flowering plant to develop Poinsettia mosaic virus (PsMV)-resistant poinsettia (*Poinsettia pulcherimma*) by expressing PsMV self-complementary CP or RdRP genes (Clarke *et al.*, 2008).

Citrus Psorosis Virus (*Ophiovirus*, Ophioviridae)

In *N. benthamiana*, hairpin RNA constructs derived from both CP and 54K genes of Citrus psorosis virus (CPsV) conferred resistance to the virus infection. In the actual host plant, sweet orange, only the CP-derived hairpin construct gave a high level of resistance (Reyes *et al.*, 2009), whereas hairpin constructs derived from either 54K or 24K genes conferred partial or no resistance. This study highlights the difference between working in model plants and actual crop plants (Reyes *et al.*, 2011).

Tomato Leaf Curl Taiwan Virus (*Begomovirus*, *Geminiviridae*) and Tomato Spotted Wilt Virus (*Tospovirus*, Bunyaviridae)

Several lines of *N. benthamiana* and tomato, transformed with a chimeric RNAi construct that consists of partial C2 gene of Tomato leaf curl Taiwan Virus (ToLCTWV) and the middle region of the Tomato spotted wilt virus (TSWV) N gene, exhibited high levels of resistance to TSWV and no symptoms of ToLCTWV after being challenged with agroinoculation (Lin *et al.*, 2011). This is an example for using a chimeric gene construct to control both RNA and DNA viruses.

Watermelon Silver Mottle Virus (*Tospovirus*, Bunyaviridae); Cucumber Mosaic Virus (*Cucumovirus*, Bromoviridae); Cucumber Green Mottle Mosaic Virus (*Tobamovirus*, Virgaviridae); and Watermelon Mosaic Virus (*Potyvirus*, Potyviridae)

Lin *et al.* (2012) developed a chimeric hairpin RNAi construct with partial sequences of N gene of Watermelon silver mottle virus (WSMoV) and partial CP sequences of CMV, Cucumber green mottle mosaic virus (CGMMV), and WMV to transform watermelon. Two transgenic lines in R_o (first generation) showed resistance to these viruses when infected either individually or in mixture. However, in R_1 the loss of resistance to CGMMV was correlated with the loss of a CGMMV-specific fragment in the chimeric transgene (Lin *et al.*, 2012). In a different approach direct repeats of the CGMMV movement protein was used to transform melon plants. Transgenic melon plants showed high resistance to CGMMV and it was correlated with the transgene methylation (Emran *et al.*, 2012). CMV resistance in transgenic tobacco expressing hpRNA construct derived from a defective replicase gene of CMV-O strain conferred immunity to both CMV-O and CMV-Y strains (Ntui *et al.*, 2013).

Potato Virus X (*Potexvirus*, Alphaflexiviridae), Potato Virus Y (*Potyvirus*, Potyviridae), and Potato Leaf Roll Virus (*Polerovirus*, Luteoviridae)

Using a chimeric RNAi construct for these three potato viruses, with partial sequences from ORF2 of Potato virus X (PVX), HC-Pro of Potato virus Y (PVY), and CP of Potato leaf roll virus (PLRV), assembled into a single transgene, conferred immunity to all three viruses in approximately 20% of transgenic plant lines (Arif *et al.*, 2012).

Alfalfa Mosaic Virus (*Alfamovirus*, Bromoviridae), Bean Pod Mottle Virus (*Comovirus*, Secoviridae), and Soybean Mosaic Virus (*Potyvirus*, Potyviridae)

Zhang *et al.* (2011b) employed several small (150bp) inverted repeats separated by single-stranded sequences to target multiple viruses instead of using one long sequence. They used sequences from the replicase gene of each of the following three legume viruses: Alfalfa mosaic virus (AMV), Bean pod mottle virus (BPMV), and Soybean mosaic virus (SMV) and combined them into a single transgene. Transgenic lines were simultaneously resistant to infection by all three viruses. The design of the construct is such that targets for additional viruses or viruses of other crops could easily be incorporated (Zhang *et al.*, 2011b).

Cassava Brown Streak Virus (*Ipomovirus*, Potyviridae)

Cassava brown streak disease is caused by Cassava brown streak virus (CBSV) or Ugandan cassava brown streak virus (UCBSV). Using hairpin RNA derived from partial CP of UCBSV, transgenic *N. benthamiana* resistant to UCBSV and CBSV were produced (Patil *et al.*, 2011). In cassava the same RNAi construct conferred resistance to UCBSV in graft experiments (Yadav *et al.*, 2011) and to UCBSV and CBSV in the field experiments (**Figure 4**; Ogwok *et al.*, 2012; Odipio *et al.*, 2013). Similarly, a hairpin RNAi construct derived from a conserved region of UCBSV and CBSV CP was used to transform both model (cv. 60444) and farmer-preferred (TME-7) cassava cultivars. Several of the 60444 transgenic lines were highly resistant to both UCBSV and CBSV. All the transgenic lines derived from TME-7, which is naturally resistant to cassava mosaic disease (CMD), showed immunity to both CBSV and UCBSV, and the immunity was maintained when

Figure 4 Tuberous roots of virus-resistant cassava (*Manihot esculenta* Crantz). Symptoms of CBSD on cassava at harvest time: (a) close-up of sections of roots of one plant of the transgenic event 718-001; (b) close-up of sections of roots of one plant of the non-transgenic cv. 60444 control; (c) close-up of the stems of one plant of the transgenic event 718-001; and (d) close-up of the stems of one plant of the non-transgenic cv. 60444 control.

co-inoculated with the East African cassava mosaic virus, one of the causal agents of CMD (Vanderschuren *et al.*, 2012). This study successfully shows the possibility to combine natural resistance with transgenic resistance to increase the range of protection.

Rice Tungro Bacilliform Virus (*Tungrovirus*, Caulimoviridae)

A mild resistance to Rice tungro bacilliform virus (RTBV) was obtained by expressing dsRNA in rice derived from ORF IV (Tyagi *et al.*, 2008).

Rice Dwarf Virus (*Phytoreovirus*, Reoviridae)

Targeting two Rice dwarf virus (RDV) nonstructural proteins (Pns4 and Pns12) by RNAi, Shimizu *et al.* (2009) obtained resistant transgenic rice lines. But lines targeting only the Pns12 gene (critical to virus replication) were also resistant to the RDV virus.

Rice Stripe Virus (*Tenuivirus*, Unclassified)

In the case of Rice stripe virus (RSV), transgenic rice expressing RNAi constructs targeting the special disease protein (SP) and the CP genes of RSV conferred stronger resistance than the lines containing either SP or CP genes alone (Ma *et al.*, 2011). In another study, both the SP and CP genes proved to be efficient in conferring the resistance to RSV in the trans genic rice plants in T_5 and T_7 generations (Zhou *et al.*, 2012). Shimizu *et al.* (2011) targeted each of the genes of RSV and found that two target genes viz., pC3 (encodes nucleocapsid protein) and pC4 (encodes viral movement protein), provided stronger resistance to RSV in transgenic rice plants.

Rice Gall Dwarf Virus (*Phytoreovirus*, Reoviridae)

Transgenic rice plants expressing self-complementary RNA from the Pns9 gene of Rice gall dwarf virus (RGDV) conferred a strong resistance to the RGDV but not to Rice dwarf virus (Shimizu *et al.*, 2012).

Rice Grassy Stunt Virus (*Tenuivirus*, Unclassified)

Similarly, in the case of Rice grassy stunt virus (RGSV), targeting nucleocapsid and movement protein by hairpin RNAi constructs resulted in a strong resistance in the transgenic rice plants (Shimizu *et al.*, 2013).

Prunus Necrotic Ringspot Virus (*Ilarvirus*, Bromoviridae)

Using transgenic cherry rootstocks expressing a hairpin RNA construct derived from the Prunus necrotic ringspot virus (PNRSV) CP gene conferred resistance to PNRSV and related Prunus dwarf virus (*Ilarvirus*, Bromoviridae) in the non-transgenic scions (Song *et al.*, 2013).

From the above examples it is obvious that PTGS-mediated virus resistance is effective against a wide range of RNA viruses in single or mixed infections, and there is great hope that these small-scale studies could be successfully replicated in the field in the near future. The examples of the transgenic papaya and the transgenic summer squash produced in the mid-1990s are still showing high levels of resistance in the fields. Some of the new resistant transgenic lines are now being evaluated in the field, for example, BGMV-resistant common bean (*Phaseolus vulgaris* L.) in Brazil and CBSD-resistant cassava (*Manihot esculenta* Crantz) in East Africa.

Control of Plant Viruses by amiRNA-Mediated Gene Silencing

There are different types of small RNAs involved in PTGS, among them siRNAs and miRNAs are the most studied (Figure 2). miRNAs are chemically and functionally indistinguishable from siRNAs but their origin and mode of action differ. Most miRNA originate from intergenic regions and a few are from gene-coding sequences and introns. Endogenous miRNAs are produced from double-stranded hairpin-like precursors formed by the fold back of primary miRNA transcript synthesized by RNA polymerase II. The stem region of the hairpin is processed into a 21nt mature miRNA duplex in a two-step process. In plants, both the steps take place in the nucleus of the cell by the action of DCL1-like proteins (Golden *et al.*, 2002; Park *et al.*, 2002). The miRNA strand complementary to its target gene is then recognized by the RISC that guides the miRNA to degrade the target mRNA (Bartel, 2004). The plant miRNA-processing machinery was used to target PPV chimera that contain the target sequence of plant endogenous miRNAs, miR171, miR167, and miR159, which resulted in reduced virus infectivity. This reduced virus infectivity was overcome in transgenic plants expressing the silencing suppressor P1/HC-Pro, suggesting that reduced infectivity was caused by the plant PTGS pathway (Simon-Mateo and Garcia, 2006). Two arms of an endogenous miRNA (21nt) on its precursor can be replaced by ~21nt target virus sequences (Fahim and Larkin, 2013). These ~21nt sequences are known as 'artificial miRNAs' (amiRNAs). If the host plant genome sequence is known, then precise antiviral amiRNAs lacking complementary host target sequences can be designed to prevent unintended off-target effects (Simon-Mateo and Garcia, 2006). Moreover, the environmental biosafety concerns of viral sequences that might complement or recombine with nontarget viruses do not apply to amiRNAs (Simon-Mateo and Garcia, 2006). Recently, amiRNAs have also been used to control plant diseases caused by both DNA and RNA viruses (**Table 2**). The general strategy has been to use modified plant miRNA precursor backbones to express 21nt sequences of viral mRNAs coding for vital proteins, including suppressors of gene silencing under strong constitutive promoters, such as the CaMV 35S.

In the first report of the use of amiRNAs to control plant viruses, *A. thaliana* miR159 precursor was modified to express amiRNAs targeting Turnip yellow mosaic virus (TYMV, *Tymovirus*, Tymoviridae) P69 gene and Turnip mosaic virus (TuMV, *Potyvirus*, Potyviridae) HC-Pro and CP genes. The expression of amiRNAs was inhibited in dcl-1 mutants, indicating that the DCL-1 protein is required for the accumulation of amiRNAs. Transgenic *A. thaliana* lines expressing amiR-HC-Pro^{159} and amiR-P69^{159} conferred resistance against TuMV and TYMV, respectively. Similarly, lines expressing amiRNAs against CP of TuMV were also virus resistant (Niu *et al.*, 2006). Transgenic lines expressing amiRNAs against both viruses in a dimeric construct were resistant to both the viruses, suggesting that resistance conferred by amiRNAs can be stacked for multiple viruses.

Similarly, CMV was successfully controlled in *A. thaliana* by expressing amiRNA (amiR-CMV-2b^{171}) in Ath miR171a precursor targeting the CMV 2b protein, a PTGS suppressor. It was done both transiently and in transgenic tobacco plants (Qu *et al.*, 2007). CMV 2b has been shown to block the movement of systemic silencing signals, to inhibit DNA methylation-induced silencing (Hamilton and Baulcombe, 1999) and also to

inhibit the AGO1 (slicer) activity (Zhang *et al.*, 2006). The resistance conferred by a 35S promoter-driven amiRNAs was superior to the U6 promoter driving a short hairpin (sh)-derived small RNA targeting the same region (Qu *et al.*, 2007), suggesting that the efficacy of amiRNA-mediated virus resistance depends not only on the amiRNA sequence, but also on the level of expression. Duan *et al.* (2008) used an experimental approach to analyze the effect of target site accessibility and engineer effective anti-CMV silencing in plants by amiRNAs. Transgenic plants expressing amiRNAs that targeted the putative DCL-mediated cleavage sites, such as those in the tRNA-like structure region, showed no protection against CMV infection. Both transgenic *Arabidopsis* and tobacco expressing amiRNAs that targeted the putative RISC accessible sites conferred a higher level of resistance to CMV challenge than those targeting the DCL-mediated cleavage sites. These findings clearly indicated that both processing of the miRNA precursor and experimentally determining accessible target sites are important criteria in designing an efficient virus control strategy (Duan *et al.*, 2008).

Transgenic tobacco plants resistant to PVX (*Potexvirus*, Alphaflexiviridae) and PVY (*Potyvirus*, Potyviridae) were obtained by expressing amiRNAs in *A. thaliana* miR159, miR167, and miR171 precursors against their PTGS suppressors TGB1/p25 and HC-Pro, respectively. Through the expression of dimeric amiRNA precursors, the resistance was obtained to both viruses in mixed infections and the resistance was maintained under laboratory conditions of high virus pressure (Ai *et al.*, 2011).

In the case of Watermelon silver mottle virus (WSMoV, *Tospovirus*, Bunyaviridae), a negative-strand ssRNA virus, six highly conserved motifs of WSMoV were targeted by amiRNAs expressed transgenically using the miR159 precursor of *A. thaliana* in *N. benthamiana* (Kung *et al.*, 2012). Two single amiRNA constructs targeting LB2 and LD motifs delayed the WSMoV symptoms or conferred moderate resistance. Transgenic lines expressing amiR-LB2 also delayed symptoms in a related tospovirus (Peanut bud necrosis virus) that has a single mutation in the target site, as it is known that amiRNAs can tolerate a single mismatch. Complete resistance was obtained when three motifs viz., LB2, LD and LC, were targeted (Kung *et al.*, 2012). Transgenic *N. benthamiana* expressing amiRNA targeting the V2 gene of Cotton leaf curl Burewala virus, a ssDNA virus, (CLCuBV, *Begomovirus*, Geminiviridae) conferred resistance to the homologous virus but not to heterologous viruses infecting cotton (Ali *et al.*, 2013).

Apart from model plants, amiRNA-mediated virus resistance has also been obtained in crop plants such as tomato, wheat, and grapevine. Zhang *et al.* (2011) showed that amiRNA-based resistance to CMV could also be obtained in tomato by targeting both coding and noncoding (3′UTR) regions (Zhang *et al.*, 2011a). The resistance was stable under high virus titer and infection with other viruses, such as TMV and TYLCV, which encode the 126-kDa replicase and AC2, respectively, both PTGS suppressors (Vogler *et al.*, 2007; Zrachya *et al.*, 2007). In another study, high to moderate tolerance was obtained against Tomato leaf curl New Delhi virus (ToLCNDV; *Begomovirus*, Geminiviridae) by two amiRNAs targeting CP (AV1) pre-CP (AV2) overlapping and CP (AV1) regions, respectively (Vu *et al.*, 2013). The study of Zhang *et al.* (2011) also indicated the cell autonomous nature of amiRNAs because there was no evidence showing amiRNAs as a systemic antiviral silencing signal, either in shoot-to-root or in root-to-shoot direction. In contrast, the virus-derived siRNAs served as diffusible antiviral signals to immunize tissues ahead of infection through phloem-mediated long-distance movement (Ding and Voinnet, 2007), and it signified the complexity of silencing by siRNAs and miRNAs (Zhang *et al.*, 2011a).

Using a modified rice polycistronic miRNA precursor (miR395), Fahim *et al.* (2012) expressed in wheat five amiRNAs targeted to the conserved regions of Wheat streak mosaic virus (WSMV, *Potyvirus*, Potyviridae) to obtain virus-resistant transgenic plants (**Figure 5**). This strategy is significant because it used a naturally existing rice polycistronic miRNA precursor. Analysis of T_1 and T_2 transgenic wheat plants revealed three types of responses, including complete immunity to the WSMV (Fahim *et al.*, 2012).

Recently, two amiRNAs constructs targeting the CP of Grapevine fan leaf virus (GFLV, *Nepovirus*, Secoviridae) were transiently expressed in grapevine. Functionality of these amiRNAs were confirmed indirectly using GUS sensor assays, but they have not yet been stably transformed in grapevine (Jelly *et al.*, 2012).

Owing to the small size of approximately 21nt, the use of amiRNAs provides many advantages over long hairpin RNA constructs, including minimal off-target effects, lower possibility of recombination between transgene and nonvirus target viruses, lower possibility of transmission by other viruses through encapsidation or by seed or pollen, or no synergy with unrelated viruses (Niu *et al.*, 2006). However, amiRNA-based resistance is susceptible to breakdown by rapid mutations in the amiRNA target sequence, especially in the seed region, change in the virus population and, by other virus isolates in case of mixed infections (Martinez *et al.*, 2012; 2013). However, these resistance breakdowns have been obtained in the laboratory by successive selection of virus progenies that mutated to overcome the resistance, and it remains to be seen if this would be the case in nature. Moreover, these concerns have also been addressed by choosing the amiRNA from the highly conserved regions (Niu *et al.*, 2006) and by stacking multiple amiRNAs for each virus in a single construct (Fahim *et al.*, 2012).

Overall, great progress has been made in the application of innate antiviral mechanism of using the amiRNA strategy to control a number of RNA and DNA viruses in laboratory/model plants, and it has opened a gateway for translating these results to crop plants.

Applications of the Post-Transcriptional Gene Silencing in the Field

Application in the field of PTGS-based technologies to induce virus resistance has been very limited so far, at least for cases where it has been shown that PTGS was the mechanism of resistance used. Papaya and Summer squash: Transgenic papaya (SunUp, Rainbow) and squash (ZW-20, CZW-3) have been employed successfully in the field with durable resistance and stability for almost two decades (Fuchs and Gonsalves, 2007). Plum: Transgenic plum is the third engineered virus-resistant product, based on PTGS, which has been successfully brought to the field (Pandolfini *et al.*, 2003; Scorza *et al.*,

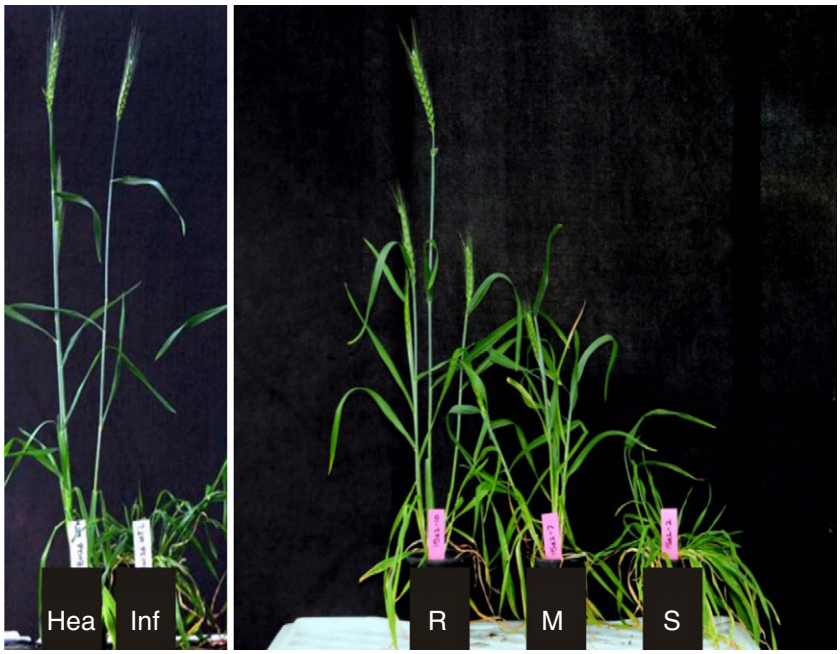

Figure 5 T_1 families of transgenic wheat (*Triticum aestivum* L.) families expressing amiRNAs. (a) Healthy and infected controls. (b) Levels of resistance in the transgenic plants. Resistance to Wheat streak mosaic virus generated by expression of an artificial polycistronic microRNA in wheat. Plant Biotechnology Journal 10, 150–163.

2001). Bean: Two transgenic common bean (*P. vulgaris*) lines transformed with the BGMV AC1 gene are likely to be the first commercial virus-resistant crops to be released in South America (Aragao and Faria, 2009). Cassava: Cassava plants resistant to brown streak disease have been developed as part of the VIRCA (Virus Resistance for Cassava in Africa) project using a hairpin RNA construct against the CP gene of CBSV and UCBSV (Ogwok *et al.*, 2012; Odipio *et al.*, 2013). So far there are no reports of evaluation of transgenic virus-resistant plants developed by amiRNA-mediated strategy in the fields.

Broad-Range Resistance by Silencing Host Proteins

The resistance obtained by PTGS seems to be specific to the virus strain from which it is derived or to very closely related strains. However, if there is a host gene that is essential for the virus replication/biology but dispensable for the host plant that could be used as a target for PTGS, and broad host-range resistance could be achieved. The eIF4E family of eukaryotic translation initiation factors of melon (*Cucumis melo* L.) were found to be essential for the replication of many viruses, mediated through the interaction with the potyviral VPg protein (Kang *et al.*, 2005; Wang and Krishnaswamy, 2012). Transgenic melon plants silenced for the eIF4E gene were resistant to four of the eight different viruses challenged, such as Cucumber vein yellowing virus (CVYV, *Ipomovirus*, Potyviridae), Melon necrotic spot virus (MNSV, *Carmovirus*, Tombusviridae), Moroccan watermelon mosaic virus (MWMV, *Potyvirus*, Potyviridae), and Zucchini yellow mosaic virus (ZYMV, *Potyvirus*, Potyviridae) (Rodriguez-Hernandez *et al.*, 2012). Similarly, transgenic tomato plants silenced for both eIF4E1 and eIF4E2 genes conferred broad-spectrum resistance to potyviruses, whereas the silencing of eIF(iso)4E resulted in susceptibility to potyviruses (Mazier *et al.*, 2011).

Suppressors of Post-Transcriptional Gene Silencing and Plant Virus Control

Suppressors of PTGS are the proteins encoded by plant and animal viruses that are used by both DNA and RNA viruses as a general strategy against the host PTGS (Voinnet *et al.*, 1999). Most of these proteins were previously shown to be pathogenicity determinants and do not share significant sequence homology among them. The success of innate and engineered PTGS against invading viruses partially depends on inhibiting these suppressors. Viral suppressors of PTGS are shown to act at one or more steps of the PTGS pathways (Alvarado and Scholthof, 2009). The mode of action of these suppressors is summarized in **Table 3**. Briefly, viral suppressors act starting from the processing of dsRNA triggers and continuing to mRNA cleavage by the AGO proteins (Alvarado and Scholthof, 2009). It has been shown that the Turnip crinkle virus (TCV) P38, the CMV 2b, and the Cauliflower mosaic virus (CaMV) P6 proteins interfere with the dicer activities, either directly or indirectly, thus preventing the processing of dsRNA into small RNAs (Haas *et al.*, 2008; Thomas *et al.*, 2003; Zhang *et al.*, 2006). The V2 protein of TYLCV was shown to inhibit the

Abbreviations: ACMV, African cassava mosaic virus; BCTV, Beet curly top virus; BSMV, Barley stripe mosaic virus; BYV, Beet yellows virus; CLCuMV-β, Cotton leaf curl Multan virus betasatellite; CMV, Cucumber mosaic virus; CRP, Cysteine-rich protein; dsRNA, double-stranded RNA; MYMV, Mungbean yellow mosaic virus; PLRV, Potato leaf roll virus; PVM, Potato virus M; PVX, Potato virus X; RHBV, Rice hoja blanca virus; siRNA, small interfering RNA; ssRNA, single-stranded RNA; TBSV, Tomato bushy stunt virus; TCV, Turnip crinkle virus; TMV, Tobacco mosaic virus; TRV, Tobacco rattle virus; TSWV, Tomato spotted wilt virus; TuMV, Turnip mosaic virus; TYMV, Turnip yellow mosaic virus.

amplification of primary small RNAs by binding SGS3 (Glick *et al.*, 2008). PTGS suppressors from Rice hoja blanca virus (NS3), from potyviruses (HC-Pro) along with the well-characterized P19 suppressor of the Tomato bushy stunt virus (TBSV), and the AC4 protein of cassava geminiviruses sequestered the small RNAs by various strategies (Anandalakshmi *et al.*, 2000; Bucher *et al.*, 2003; Chellappan *et al.*, 2005; Lakatos *et al.*, 2004). The TBSV P19 and the P1/HC-Pro of Turnip mosaic virus (TuMV) also affected the stability of small RNAs by interfering with the function of HEN1, a methyl transferase (Lozsa *et al.*, 2008; Yu *et al.*, 2006). Similarly, the 126-kDa protein of TMV and the P21 protein of BYV interfered with the HEN1 activity (Vogler *et al.*, 2007; Yu *et al.*, 2006). Finally, the polerovirus (Beet western yellows virus) P0 protein and the CMV 2b protein) interfered with the slicer activity of AGO1 protein (Pazhouhandeh *et al.*, 2006; Zhang *et al.*, 2006).

Range, Level, and Stability of Gene Silencing-Based Virus Resistance

The virus resistance conferred by gene silencing is highly sequence specific to the cognate virus strain from which the dsRNA trigger is derived and to related strains depending on the sequence identity. Most of the studies reported have not tested their PTGS constructs against related strains or viruses. A few previous studies indicate that sequence identity of 89% or higher is sufficient to confer resistance to related strains (Jones

et al., 1998; Lindbo and Dougherty, 1992). However, in a recent report a hairpin RNAi construct derived from HC-Pro gene of ZYMV conferred resistance in cucumber to WMV and PRSV-W with 67% and 63% sequence identity to HC-Pro, respectively (Leibman *et al.*, 2011). Similarly, a hairpin RNAi construct derived from a partial CP gene of UCBSV conferred resistance to both homologous and heterologous strains of UCBSV and even to isolates of a different species CBSV, in *N. benthamiana* and cassava (Ogwok *et al.*, 2012; Patil *et al.*, 2011). The cross-protection could be explained by the observations that functional siRNAs and miRNAs can tolerate a few mismatches in non-seed region (~7–9 bp). It has also been shown that the resistance to cognate virus is sometimes affected by another virus in mixed infection. In barley, the resistance to BYDV-PAV was not broken down by an unrelated virus species in the mixed infection with CYDV-RPV (Wang *et al.*, 2000), whereas in the case of Potato virus A (PVA, *Potyvirus*, Potyviridae) the resistance to a cognate virus (PVA) was broken down after infection by Potato virus Y (PVY; *Potyvirus*, Potyviridae) (Savenkov and Valkonen, 2001). The range of protection could also be increased by combining transgenic PTGS-mediated resistance with naturally available resistance in some crops, such as cassava (Vanderschuren *et al.*, 2012).

Regarding the level of virus resistance conferred by gene silencing, it is ranging from partial resistance/delayed symptoms to immunity. For both DNA and RNA viruses, immunity to inoculated virus has been obtained by hairpin RNA-mediated resistance in several cases. For example, a single copy of BYDV-PAV polymerase (Wang *et al.*, 2000), line 126 of tomato that contains TYLCV-C1 (Fuentes *et al.*, 2006), line 5.1 of common bean that contains BGMV-AC1 (Bonfim *et al.*, 2007), and line 718.001 of cassava that contains UCBSV-CP1 (Ogwok *et al.*, 2012) all are immune against their cognate viruses. The key is probably to select effective regions of the virus for the hairpin RNAi construct because all regions of the virus genome are probably not equally effective for virus resistance. In addition, by employing different (non-PTGS) resistant mechanisms the level of resistance can be increased (Pavli *et al.*, 2010).

In most of the studies reported using PTGS for virus resistance, the level of transgene expression assessed by the level of target siRNAs produced were not analyzed. It has been demonstrated in the case of the CBSV and UCBSV, in both tobacco and cassava, that there is a correlation between level of expression and the level of resistance (Patil *et al.*, 2011). It could also be possible that the level of expression affects the broad-range protection, by increasing the number of target siRNAs that could potentially prime a nontarget virus (e.g., UCBSV vs. CBSV).

Stability of transgenic virus resistance is a very important requirement for the successful deployment of field resistance, especially in the case of perennial crops. A number of studies have shown the stability of PTGS-mediated virus resistance over several generations and years. Noticeably, papaya, the first commercial product for virus resistance, is still highly resistant in the fields (Ferreira *et al.*, 2002; Fuchs and Gonsalves, 2007). In the case of BGMV, resistance in common bean (*P. vulgaris* L.) line (5.1) for more than 2 years of field trials has confirmed the greenhouse observations of resistance to this virus. Sequencing the target region of line 5.1 in several Brazilian isolates has shown 100% identity or less than one point mutation within the transgene (Aragao and Faria, 2009). The C5 line of plum transgenic for the CP gene was uninfected for more than 4 years in the field with natural aphid vectors, whereas susceptible and non-transformed trees developed severe symptoms within the first year of the study (Hily *et al.*, 2004). It remains to be seen, however, what happens to the resistance when the C5 line of plum is coinfected with multiple PPV strains and with other viruses. In the early field trials of CBSD-resistant cassava, line (718.001) has shown stable resistance for more than two seasons (Odipio *et al.*, 2013). Similarly, several previous studies involving CPMR, many of which were shown later using PTGS, have demonstrated a long-term stability of virus resistance. For example, ZW-20 and CZW-3 lines of summer squash (*Cucurbita pepo* spp. *ovifera* var. *ovifera*) have shown stable and durable resistance for more than two decades (Fuchs and Gonsalves, 2007). Transgenic papaya that contains PRSV CP (Rainbow) has shown to perform well in Hawaii for more than 20 years (Fuchs and Gonsalves, 2007). Therefore, it appears that PTGS-mediated virus resistance would be stable in the fields for very long periods of time.

Future Challenges

The major challenge of the PTGS strategy is the high level of sequence specificity required for degradation of target RNA. This problem is more critical in amiRNA and shRNA constructs than for longer dsRNA constructs. Viruses exist as populations in the field, and mutations in the seed region of the effective small RNAs might result in the breakdown of the resistance. For example, in a study with closely related isolates of CTV, PTGS was highly strain specific and not effective against closely related strains (Febres *et al.*, 2008), whereas for cassava, geminivirus protection was obtained against related virus species (Chellappan *et al.*, 2004). The cross-protection is thought to be conferred by the so-called 7bp 'seed region' of the small RNAs (Lewis *et al.*, 2003). One of the solutions for this problem is to select highly conserved regions of the genes such that mutations in those regions will be lethal to the virus, or by stacking multiple regions of a virus under a separate promoter – or under a single promoter as in the case of polycistronic amiRNA construct used against Wheat streak mosaic virus (Fahim *et al.*, 2012).

Another major challenge is the suppressors of gene silencing that interfere with the host PTGS at one or more steps. In the case of mixed infections, these suppressors are shown to act synergistically and increase the severity of the disease (Vanitharani *et al.*, 2005). For example, transgenic tobacco resistant to PVA became susceptible to PVA after Potato virus Y (PVY) infection (Savenkov and Valkonen, 2001). To be successful under field conditions, PTGS technology has to take into account the prevalence of virus species and their interaction in the host plant besides targeting the sequences of suppressors of gene silencing in the RNAi constructs (Yadav *et al.*, 2007). The breaking of PTGS resistance for a virus by an unrelated virus, as reported by the studies conducted in the laboratories, is less likely to happen in the real field conditions. This can be further avoided by stacking genes of

viruses prevalent in a given geographical area in the design of the hairpin RNAi construct.

Although PTGS technology for plant virus control has been successfully demonstrated in the laboratory against a large number of diverse RNA and DNA viruses, so far only a few studies have been successfully applied under field conditions. Moreover, many studies have been conducted on model plants, such as *N. benthamiana*, *A. thaliana*, or on cultivars responding to tissue culture. Only in the recent past have a few studies been carried forward to the field evaluation, for example, PPV resistant plum in the United States, BGMV-resistant common bean in South America, and Cassava brown streak disease (CBSD) resistant cassava in East Africa. Individual viruses are often less damaging than their synergistic effects in the mixed infections. The field conditions vary widely both in biotic and environmental factors, such as presence of other viruses or strains of the same species as well as light, temperature, humidity, etc. Consequently, these factors, such as biodiversity of the viruses, need to be incorporated into the project right from the beginning. On a laboratory scale, resistance has been obtained against multiple viruses and there are still many opportunities to stack the genes for multiple virus or pathogen resistance. Ultimately, there is an urgent need to translate these findings into field conditions. Many times this requires collaboration among scientists of different disciplines, such as biotechnologists, plant breeders, and plant pathologists, from the public and the private sectors.

Because most of the studies performed and reported provide partial information relative to the PTGS mechanism involved, the length and 'value' of the target sequence, the level of expression, the level and range of resistance obtained, and the stability of this resistance in time and space, it is difficult to have a realistic opinion about the strength, validity, and usefulness of such technology for so many different types of viruses in so many hosts, in various places in the world. There are, however, a few common features that are worth noticing; PTGS has been shown to induce virus resistance for many viruses of RNA and DNA nature, in different types of hosts, which seems to indicate that this technology has a universal capacity, provided it is well developed to produce significant and long-term virus resistance for many hosts. The fact that very few products have been or are being deployed is due to a variety of reasons that are not scientific but rather economical or social. The virus targets are either not commercially supported (cassava and rice) or are not big enough (vegetables and fruits) to warrant development by the private sector, leaving the public sector to make all the necessary development, including biosafety regulations that are not in place in many countries in the world. Finally, the opposition of certain groups of growers or the public to adopt this technology is also impacting the development of this technology, such as for fruit trees and vegetables, where the organic market is now driving the decisions.

Glossary

Cold chain Set of facilities for keeping a product cool or cold from farm to market.
Comparative advantage Inherent ability to produce and sell in international markets at prices equal to or below those of competitors from other countries, abstracting from policy interventions such as taxes and subsidies.
Competitive advantage The same as comparative advantage but evaluated at prevailing prices including the effects of policy interventions.
Covariance risk The risk that variables may move together, for example, yields for several crops in an area may decline when a drought strikes.
Guarantee fund A fund set up to guarantee part of a loan, so that in the event of default the lender recovers at least part of the funds lent.
Multiplier effect The total effect on consumption in the economy of the successive rounds of spending induced by an initial increase in income in a sector or district.
Social capital The ability of individuals (producers in this case) to work together to achieve common aims that could not be achieved without cooperation.
Usufruct right A recognized right to utilize a natural resource, such as land or forests.
Value chain The entire chain of a product from producer to market, from genetic material (in the case of agriculture) through production and harvest, postharvest management, storage, transportation, processing, packaging, and marketing.

Introduction

The Role of Agriculture in Economic Development

In the early strategies for economic development, the role of agriculture's contribution to national growth was conceived as passive. Its primary role was to release resources for use in other sectors: labor and savings (e.g., Chenery and Syrquin, 1975). A supporting role was to generate foreign exchange earnings for use in purchasing imported inputs for industrial growth. Now it is recognized that agriculture's role is more active, and that through its role in reducing poverty and its multiplier effects on domestic demand, it can be one of the motors of economic development. As Mellor (2000) put it:

> Typically high growth rates are achieved when agriculture grows rapidly. That is because the resources used for agricultural growth are only marginally competitive with other sectors and so fast agricultural growth tends to be additive to growth in other sectors… Block and Timmer's model of the Kenyan economy shows the multipliers from agricultural growth to be three times as large as those for nonagricultural growth.

It has been found that agricultural growth is not only the most effective way to reduce rural poverty, but that it is also more effective than industrial growth in reducing urban poverty. To cite one of the several international studies on the topic, Peter Timmer's analysis of a sample of 35 countries found that

> A one percent growth in agricultural GDP per capita leads to a 1.61 percent increase in per capita incomes of the bottom quintile of the population in 35 developing countries. A similar one percent increase in industrial GDP increases the incomes of the poor by 1.16 percent (Timmer, 1997; a fuller discussion of these points is presented in Norton (2004, Chapter 1)).

Agriculture has been a driver of growth in industrialized countries as well: "The growth of total factor productivity in the OECD countries in agriculture has been greater than in manufacturing during the past quarter century or more. The difference has not been small" (Johnson and Agriculture and the Wealth of Nations, 1997, pp. 9–10).

The role of agriculture in earning foreign exchange continues to be relevant for many developing countries, and given that it is a major user of natural resources (land and water and also forests), agricultural development must be sustainable in its resource management. In brief, the most vital roles of agriculture in supporting the development of the entire economy are

- providing increased food security for rural populations, through both higher per capita rural incomes and production of food for home consumption;
- reducing poverty;
- contributing to stimulating the nation's economic growth;
- generating export earnings; and
- assuring the sustainable management of the natural resource base.

The overarching objectives of agriculture policy are the strengthening of each of these roles, for the benefit of the entire economy and nation. The Comprehensive African Agricultural Development Program, an African-led effort under the aegis of the New Partnership for Africa's Development (NEPAD), places agriculture at the center of strategies for reducing poverty and achieving the other Millennium Development Goals of the United Nations (NEPAD Planning and Coordinating Agency, 2010).

Identifying Agricultural Potentials and Constraints

For the sake of efficiency, sound economic policy should strive to make effective protection rates as uniform as possible across products, on the assumption that producers will expand

output of the most competitive ones. However, in a world of many products and many small farmers who may have experience with only a few products, government programs often try to introduce the most promising products to farmer groups and facilitate the adoption of those products. How are the products identified? One step is to look to export markets. Developing-country exports are usually labor intensive and therefore their growth helps create employment and reduce poverty. Nevertheless, promoting exports successfully requires exploiting comparative advantage.

The challenge for policy and for the private sector is to find comparative advantage and turn it into competitive advantage. Following Porter (1990), competitive advantage can be gained either through cost competitiveness or through product differentiation. In agriculture, differentiation by product quality as well as by type of product is an important consideration in determining competitive advantage. Identifying potentials empirically is complicated by the fact that comparative and competitive advantages are dynamic. They can change rapidly because of both external and internal factors. Mexican cotton disappeared because of increasing costs of pest control in cotton-growing zones. Costa Rican pineapple gained markets because of technology (varieties) and marketing support. Colombian coffee has been losing market share because of lower costs of production in Vietnam and Brazil. Peru went from virtually zero production of asparagus to its world's largest exporter in a few years, in part, because of the opportunity to harvest the crop year round.

Classical methods of calculating comparative advantage, such as the domestic resource cost coefficient, do not capture dynamic factors. Approaches such as the revealed comparative advantage capture past trends but ignore cost-price comparisons. Therefore, empirical methods are often used in agriculture to identify products with competitive advantage or the potential for it, such as

- products in which the country has a recognized quality advantage or can meet international quality standards while remaining competitive on costs (e.g., papaya in Belize, gooseberries in Colombia, and macadamia in Rwanda and Malawi);
- products for which the country was a major exporter in the past (it has to be asked why the exports declined and if the factors involved can be reversed);
- consensus opinions in the private sector: producers, processors, and marketing agents; and
- products with proven potential (on the basis of experience of some producers) for significant improvements in yields and quality.

Above all, in agriculture the value chain has to be analyzed and satisfactory responses are needed for questions all along the chain, from seeds to markets: Are the varieties that farmers plant are the same that the market demands? Is there sufficient volume of disease-free, high-quality planting material? Do farmers cultivate and harvest according to best practices (including harvest timing and selection of the products ready for harvesting)? Do postharvest practices maintain quality (drying, threshing, storage, classification and selection, and initial processing in some cases)? Are transport links and facilities available, including cold chain facilities, that will prevent damage to the products when moved to markets or marketing agents? Are plant or animal hygiene standards met all along the chain? Do processing facilities meet international standards? And so forth. When one or more of these questions is answered negatively but the potential appears to be present, it has to be asked if policies and programs can overcome the bottlenecks at a reasonable cost.

The importance of developing competitiveness along the full value chain has been emphasized in many studies for all regions of the world, as in the following:

> The entire value chain is critical: The need to maintain grades and standards within the value chain, not only in export markets but also in evolving domestic and urban markets, drives innovation in agribusiness… Quality assurance, driven by the search for competitive advantage with domestic markets of access to export markets, in turn requires coordination along the value chain… (Kim *et al.*, 2009, p. 10).

Maintaining competitive advantage over time is another challenge and requires

- continuous adaptation of technology, seeking improvements in yields, reduction in costs, and improvements in quality;
- continuous contact with markets to perceive rapid changes in market preferences and requirements;
- integration of the chain of production, postharvest handling, transport, marketing, and in some cases processing; and
- continuous improvements in public infrastructure, institutions, and policies that support production.

In spite of today's ease of international transport, comparative or competitive advantage sometimes exists not only by product but also with respect to market locations. For example, countries in Eastern Africa and the Indian Subcontinent would have a leg up on the competition in serving markets in the Gulf States and the Middle East.

Agriculture and Rural Development

Agriculture is one instrument of rural development. By raising rural incomes, it provides a basis for broader rural development. However, agriculture alone usually cannot satisfy the requirements for more rural employment and higher living standards. Sources of nonagricultural rural employment are needed along with, over long periods of time, rural–urban migration in quantities that the urban job market can absorb.

Development of high-value products, addition of family livestock, and integration of farmers more fully into value chains can accelerate the generation of nonfarm jobs in rural areas. In all regions of the world, agriculture is becoming a more knowledge-intensive industry and its expansion creates demand for specialized services, including input supply, market information and product development support, business management and consulting, transportation and logistics, quality assurance (including certifications), skills, extension and training, veterinary services, and credit and other financial services. To this list can be added irrigation development and management, paraveterinary services, machinery rental and

repair, product selection and packing jobs, administration of cooperatives and farmer associations, soil analysis, local agricultural processing and associated management of facilities such as cooling centers, and others. Although financial services may originate from urban financial entities, they are provided through rural branches and increasingly through local savings and loan associations and microfinance entities. The role of high-value crops in promoting rural employment generation has been noted by Weinberger and Lumpkin: "If… horticultural production increases, this can lead to increased employment opportunities and rising wage levels. Both can be induced either because of increasing labor demand at the farm level, at the level of input providing industries, or at the level of processing and postharvest industries" (Weinberger and Lumpkin, 2007, pp. 1468–1469).

The demand side of the rural economy also plays a role in fostering the growth of rural nonfarm economy: "technological change in the Rural Non-Farm Economy occurs most frequently in rapidly growing rural regions; growing local demand in the rural economy seems to increase opportunities for market growth and attracts new entrepreneurial activity and investment.…" (Haggblade *et al.*, 2009, p. 17).

Training is required for these many specialized activities and occupations. In addition, the small size of many farms mandates cooperation as a prerequisite for participating in higher value markets, and hence the development of social capital is another requirement. As well as endowments of suitable farmland, successful rural development requires progress along the four axes of 'private' and 'social' forms of human and physical capital:

- Individual knowledge and skills, usually termed human capital.
- Ability to work effectively and productively in groups, or social capital (considerable work has been done in conceptualizing and measuring social capital, e.g., Grootaert and van Bastelaer, 2002).
- Private physical capital or farm improvements, such as cultivated terraces, wells, fencing, stables, storage bins, etc., plus stocks of livestock and plantings of tree crops.
- 'Social' physical capital, which includes jointly owned assets (e.g., cooperative processing facilities) and infrastructure supplied by the state, such as roads, publicly supported irrigation systems, electricity, and health facilities.

Agricultural development can promote, and be the result of, increases in these kinds of capital. Higher levels of human and social capital can be utilized in nonagricultural occupations. These four axes are not alternatives for rural development; serious deficiencies in one of them can hinder the overall progress. Hence, development policy needs to promote advances on all four axes.

As an example of the effects of progress along these axes, for many years international development agencies had refrained from supporting road development, but studies have repeatedly shown that the rate of return to rural roads is very high (although there can be concerns about the environmental consequences of road penetration into unsettled areas). In a recent study, Webb (2013) showed the strongly stimulating effect on rural incomes of simple, all-weather farm-to-market roads in the Peruvian highlands, areas that have been difficult for development.

The Nature of Agricultural Policy Instruments

Agricultural policy is implemented through five kinds of instruments: (1) new legislation, (2) executive decrees, (3) investment projects, and (4) programs, which usually require significant numbers of field staff working with farmers, input supplies, processors and the like, and (5) voluntary collaboration by the private sector. Instruments may be combined; a program may have an investment component, or may require an executive decree before it can be carried out. Legislation and decrees define the rules of the game and establish programs, such as guarantee funds, subsidies targeted on the poor, and the formation of water user associations, among many other examples.

Broad Issues in Agricultural and Rural Policy

Macroeconomic Policy and Agricultural Development

Macroeconomic policy affects agricultural growth prospects, mainly through three instruments: the exchange rate, trade policy, and fiscal policy. Real prices in the agricultural sector are unusually sensitive to the exchange rate because agriculture is a highly tradable sector. It is a major exporter in many countries, and its imports often compete with domestic production, either directly or indirectly through substitution effects in consumer diets. Hence, it has been long accepted that an appreciating exchange rate in real terms brings about a decline in domestic real agricultural prices (two of the earliest studies to document this relationship empirically were Krueger *et al.* (1988) and Schiff and Valdés (1992)). This is not only a question of incentives for growth, but, for many smallholders, a decline in real prices signifies worsening malnutrition.

In most countries, the exchange rate is the main determinant of relative, or real, prices in agriculture. This issue is sufficiently important that the UN Food and Agriculture Organization has stated:

> The maintenance of overvalued exchange rates is of particular significance as they impose a tax on exports and subsidize imports. This tool has been used at a high cost to stabilize and hold down domestic food prices for urban consumers at the expense of the domestic producers of import-competing and exportable agricultural products… (FAO, 1996, p. 294).

Trade policy, principally in the form of tariffs and nontariff barriers, affects real prices also, but usually in the direction of raising them (an exception to this statement has been the practice of eliminating tariffs on food aid imports when for all other products there is at least a standard tariff even if a low one; this kind of policy constitutes price discrimination against producers of the commodities concerned), and sometimes with the result of creating uncompetitive, unsustainable subsectors in agriculture. However, protectionist policies tend to be found more in the agriculture of developed nations than in developing nations, so the concern among the latter is to reduce world levels of trade protection.

Developing agriculture generally pays less in taxes because incomes are lower than in urban areas, so fiscal policy concerns outlays from the government budget. In this area, a large number of issues arise about the priorities for such outlays and their effectiveness in stimulating sustainable growth paths in the sector. Some of these questions are treated in the remaining sections of this article.

The Role of Government and the Private Sector

In agriculture, in a developing market economy, the role of the government is complex, sometimes so much so that it places a heavy management burden on the capacity of a Ministry of Agriculture. Among other things the government is responsible for

- setting fair and transparent rules of the game and enforcing them;
- providing special assistance to bring the poor and marginalized into the ambit of economic development;
- providing economic leadership and programs to catalyze the sector;
- facilitating private sector growth, through public–private partnerships, financial guarantees, assistance in organizing producer groups, and the like;
- providing public goods (a worthwhile discussion of the differences between public and private goods in agriculture is found in Umali-Deininger (1997)), such as infrastructure, some kinds of agricultural research, etc., in which the private sector would underinvest or not provide (e.g., land registries);
- ensuring that other vital productive services are available, from the private sector or if necessary from the public sector (e.g., irrigation water and seed multiplication services in the early stage of developing a private seed network);
- providing assistance for emergencies; and
- mediating conflicts over natural resources and other issues.

Developing and enforcing fair and transparent rules of the game can lead the government into an uncomfortable situation of managing conflicts among interested parties. In this area, central roles of the public sector are to provide

- secure property use rights and clear rules for access to property (land, water, and forests);
- informative guidelines for contracts (land rental, exchange of water use rights, sale of products, and borrowing capital) and swift and impartial enforcement of contracts; and
- clear system of weights, measures, and standards in product markets.

In the area of help for the poor and marginalized, governments may provide

- targeted subsidies for access to land, water, inputs, and extension advice;
- targeted programs of microcredit or seed capital for them;
- participatory agricultural research and extension, involving farmers and using their plots;
- grants for acquiring livestock and tree crops or for covering part of their cost;
- assistance in farmer organization;
- training in marketing and facilitation of links to private buyers and exporters; and
- payments for natural resource management under payments for environmental services schemes.

In regard to economic leadership and facilitation, some examples of public sector roles are the following:

- Fundación Chile created state companies for new technologies and products, launched them, and then sold them to the private sector.
- In Peru, competitive grants have been awarded to groups of small farmers to cover the costs of entering new markets.
- In Rwanda, international specialty coffee buyers were brought into the country to develop links between them and coffee-producing cooperatives.
- Governments sometimes provide seals of quality assurance, or support programs for them, for products sold in foreign markets.
- Competitive grants are given for agricultural research by academic institutions, farmer organizations, nongovernmental organizations (NGOs) and the private sector as well as national agricultural research centers.
- Competitive grants also may be awarded to cofinance small irrigation systems built by farmer groups and NGOs (e.g., Chile).
- Simplifying bureaucratic regulations helps the private sector.
- Helping train and organize farmers, of funding such efforts, facilitates private initiatives.

Many developing countries have experienced takeoffs in their agricultural sectors in recent years, especially in Africa and parts of Latin America. However, continuing agricultural development often requires a progressive shift in the roles of the public and private sectors. The latter needs to take greater responsibility for value chain development: for investments, management of facilities, quality control, farmer advisory services, input marketing, irrigation management (often through water user associations), and many other tasks. This need has been formally recognized in Africa with the recent establishment, under the leadership of the World Economic Forum, of a program called New Vision for Agriculture/GROW Africa, with the express purpose of linking entrepreneurs with producers and identifying promising opportunities. The public sector needs to make it clear that it is withdrawing from these areas and honor that commitment, and at the same time play an effective monitoring and regulatory role including for food hygiene and safety. It can act as a facilitator for partnerships and key actions. Fertilizer is a case in point in which sometimes voucher schemes or other forms of subsidy are used to encourage input uptake on the part of smallholders, and in those cases the allocation and use of input vouchers or other forms of subsidy needs to be consistent with development of a private distribution network and it requires careful supervision.

Often the private sector is better placed to assess markets and to commit resources on the basis of those assessments. It is hard to overstate the importance of promoting a leading role for the private sector in agriculture and, by the same token, inculcating a business attitude in farmers. Passing the baton to

the private sector for many actions has implications for the allocation of public resources in the sector. For example, to facilitate and encourage greater private sector involvement, transitional public sector support and outlays may be needed for programs like the following, among others:

- Training programs in entrepreneurship and cooperative management.
- A venture capital fund for new enterprises and market development in agriculture. An example of a venture capital fund for small agricultural entrepreneurs is Impulso Panamá, put into operation in that country in 2008 with the support of the Inter-American Development Bank. Earlier, the IDEA project in Uganda (a project to link farmers to markets supported by the United States Agency for International Development) also provided grants for business development at crucial points in agricultural value chains. For a discussion of designing and implementing these innovation funds, see The World Bank, Agriculture and Rural Development Department (2010).
- Risk-reducing guarantees for contract farming relationships.
- Sharing the cost of agricultural advisory services; although in many cases they can be contracted by farmer organizations, they can be partially or wholly supported financially by the government in the medium term.
- Public–private partnerships for postharvest activities.

Given these demands on public sector resources, the development of partnerships with the private sector takes on increasing urgency. Equally, it is important that public resources be channeled to the sector in ways that are designed to promote efficiency in the sector. This means targeting support on actions that have sector-wide reach, such as infrastructure development (including irrigation, roads, and land terracing), strengthening human capital, and carrying out interventions that catalyze private sector commitment of resources.

Governments may also present to the private sector opportunities for building irrigation schemes and for leasing nonirrigated land, with benefits to farmers who are already on the land. This kind of participation from the private sector accelerates the construction of needed infrastructure in the sector, introduces new production technologies, and increases production while ensuring that farm household incomes reflect the benefits of the projects.

When there are indications of private interest in fostering growth of particular horticultural products or other export crops, at early stages in the development of these subsectors public sector resources may be effective in providing short-term guarantees to both farmer groups and exporters in order to encourage them to enter into contracts for growing horticultural crops, with technical assistance provided by the exporters. Equally, public support can be effective for private sector market exploration missions and for gathering information on quality standards (grants for market exploration and other activities by smallholders and small-scale rural entrepreneurs were also provided by the Impulso Panamá fund).

Growth among smallholders raises questions of scaling up volumes, because for marketing and other purposes smallholders need to combine their efforts and output. The traditional approach to scaling up has been to stimulate the formation of cooperatives of farmers who agree to plant their contiguous plots in the same crop. That has worked well in many cases, particularly in irrigation schemes and on hillside terraces, but the cooperative approach needs to be complemented with technical assistance in production and marketing, as well as management training for cooperatives and marketing assistance. Hence, it is demanding of resources. For this reason, alternative models for scaling up have been explored, including a model in which entrepreneurs lease land from groups of producers, contract (outgrower) farming, and the nucleus farm model. They may require supervision and guarantees that farmer land rights and incomes are protected.

A guiding principle for public expenditures is for the government to orient its support toward development of basic growth factors (physical infrastructure and human capital); toward transitional programs to stimulate innovation in products and product handling, processing and marketing; toward encouragement of entrepreneurial initiatives in the sector; toward increasing human and physical capital endowments of smallholders and landless families; and toward sharing investment costs with the private sector when necessary, always under an exit strategy for the public sector.

Pricing Policies

Many countries have experimented with controls on the prices of basic commodities but they have almost invariably ended up abandoning them sooner or later. They have a role in temporary emergency situations, but in the longer run they usually prove untenable. In the first place, it is impossible to calculate continuously what a market equilibrium price would be, so administered prices have the effect of generating either shortages or surpluses of each commodity controlled. Second, they do not send appropriate price signals to producers in terms of the relative worth of different commodities, so they tend to lead to misallocations of resources. Generally, price controls are biased in favor of consumers, so the net result is a shortfall of domestic production, and in the long run that tends to defeat the aim of reducing inflation through the controls. A study of the transition from planned to market economies in Eastern Europe reached the conclusion that setting prices free actually leads to lower inflation than a policy of price controls (de Melo *et al.*, 1996).

Agricultural marketing boards have tended to work more effectively in East Asia and some countries of South Asia, than in Africa and Latin America. In this case, effectiveness is measured by the extent to which they actually deliver the announced purchase price to farmers, and their efficiency in handling and selling the products.

Industrial crops such as cotton and sugar, in which there are economies of scale in processing, present a special case in which prices can be distorted by monopolies or oligopolies. In African cotton, there has been a movement away from national processing monopolies toward local monopolies, and this has engendered a degree of competition in the sector. The concern is not only for the level of prices to growers, who only in some cases have a realistic option of shifting to other products, but also for the long-term viability of the processors.

In the end, adequate pricing for these products will depend on governance structures within the sectors.

> Price setting needs to occur in a framework of negotiation, but rules must continue to be reformed to provide reasonable assurance to companies that, if they operate efficiently according to international standards, they will be able to earn a reasonable return on their investment over time. Some level of price flexibility over the course of the marketing season may need to be a part of the revised pricing approaches (Tschirley *et al.*, 2009, p. 176).

Sugarcane presents a more challenging case because it is more difficult for an individual producer in a large cane-producing area to switch to another crop. Here price negotiations with large groups of farmers are routine, and it has been important to move toward pricing systems based on the sugar content of the cane rather than the raw tonnage of cane. It also helps the negotiation process to use as benchmarks international data regarding the ratio of the cane price (to producers) to the processed sugar price.

Gender in Rural Development

In rural areas throughout the developing world, women have more burdens on their time than men do. They are responsible for household management and tasks, for households gardens and small ruminants, and they till fields and work on land improvement projects as much as men do. In South Asia, for example, 60.5% of women work in agriculture as opposed to 42.9% of men. In the flower sectors in Colombia and Mexico, 60–80% of the workers are women, and in the Ugandan flower sector they are 85% of the workers. In Sinaloa, Mexico, women represent 40% of the field workers and 90% of the packers; in the Chilean fruit sector they are 50% of the temporary workers. In the vineyards in Northeast Brazil, women represent 65% of field workers (The World Bank, FAO and IFAD, 2009, pp. 320–321). These examples can be replicated over and over.

In spite of their high rate of participation in agricultural activities, women almost uniformly have fewer legal rights to land, less say in irrigation allocations, and weaker decision power over input purchases and field cropping choices, as well as generally lower rates of participation in farmer groups. Women's rights to land may be severely circumscribed even in customary forms of land tenure, more so if they are unmarried, widowed or divorced, and when modern land titling is introduced in a traditional society often land is titled in the name of the household head, who usually is assumed to be a man. Women often lose the land rights they may have had when modern land registries are introduced (The World Bank, FAO and IFAD, 2009, p. 136).

Recent decades have seen a movement toward greater gender equity at least in legislation affecting rural women:

> Many nations have… modified land and property laws and regulations so as to guarantee women's equal property and inheritance rights… most Latin American nations passed legal reforms in the 1980s and 1990s to remove discriminatory clauses applying to family… and inheritance. They also modified land allocation laws and regulations (e.g., for agrarian reform and land titling programs) to recognize and give women equal land rights explicitly. Similar movements in reform legislation occurred in Africa and Asia (The World Bank, FAO and IFAD, 2009, p. 126).

However, "enforcement of these laws is sporadic, and attempts by women to have the law enforced can be painfully difficult" (The World Bank, FAO and IFAD, 2009, p. 127).

Notwithstanding all these barriers, women are generally more productive than men in agriculture and use limited resources more effectively for reducing poverty. A compilation of case studies by the World Bank brought out the following conclusions:

- Burkina Faso: Shifting labor and fertilizer between men's and women's plots could increase output by 10–20%.
- Kenya: Giving women the same inputs and education as men could increase yields by more than 20%.
- Tanzania: Reducing time burdens for women could increase cash incomes for smallholder coffee and banana growers by 10%.
- Zambia: If women enjoyed the same overall degree of capital investment in agricultural inputs, including land, as their men counterparts, output in Zambia could increase by up to 15% (The World Bank, FAO and IFAD, 2009, p. 3).

Women have also proven to be more reliable clients of microfinance organizations. A study of microfinance in Bangladesh found that:

> Microfinance reduces poverty by increasing per capita consumption among program participants and their families. Annual household consumption expenditure increases Tk 18 for every Tk 100 of additional borrowing by women and Tk 11 for every Tk 100 of additional borrowing by men… Women have proved to be excellent credit risks with loan default rates of only 3 percent – significantly lower than the 10 percent default rate for men (Khandker, 1998, pp. 146–147).

In short, reducing gender bias in agricultural programs is not only a question of fairness but also a significant source of new agricultural growth and improvements in rural household welfare. Programs for this purpose have been introduced throughout the world, and they often start with gender assessments of existing institutions and programs, and move on to issues of how to target women more in agricultural extension services (e.g., dealing with women in groups and employing more female extension agents), bring them into cooperative leadership roles, and the like. The cited Gender in Agriculture Sourcebook is a valuable reference for initiatives in this area.

Policies for Basic Agricultural Resources: Land, Water, Financial Capital, and Technology

Land Tenure Policies in Rural Areas

The importance of land tenure and its policy objectives

Land tenure arrangements everywhere are one of the foundations of agricultural production and natural resource management. The many issues concerning land tenure regimes for agriculture can be grouped around two overarching themes: security of land tenure and access to land. Institutional

frameworks can provide powerful incentives for productive activity, as much as prices can, and land tenure regimes are a preeminent example of such frameworks.

Equally, adequate tenure provisions for forested land, and land to be reforested, can provide incentives for sustainable forest management. Experiences in many countries (Congo, Cameroon, Panama, Ecuador, and Indonesia, among others) have shown that the greatest forest depredations tend to occur when usufruct rights to forests are not clearly defined and administered.

Access to land is one of the most valuable instruments for reducing rural poverty, although it is not a panacea in this respect. Both traditional land tenure systems and governments have emphasized providing access to land for poor rural families.

For land tenure, more than other fields of agricultural development policy, viable approaches depend on the historical and social context of each country. Land tenure is often one of the most heated subjects in agricultural development policy. Whether land is effectively and sustainably used has a strong bearing on agricultural growth and rural poverty. Land ownership often is highly contested and ownership or usufruct rights can be uncertain. In these settings the following policy objectives, sometimes conflicting, tend to govern land decisions:

- Achieving economically efficient allocations of land and conditions of tenure, to provide incentives for production.
- Ensuring equity (fairness) in allocations of land.
- Helping reduce rural poverty by providing poor families with a productive asset.
- Promoting sustainable environmental management of the land resource.

In developing countries the broad issues of land tenure frequently include some of the following:

- How can access to farmland be provided for landless rural families and those with tiny plots?
- How can equity in land distribution be made consistent with productive commercial farming?
- How can farmers be provided long-term security of rights to use farmland, to give them incentives to invest in the land?
- How can grazing rights be made secure and, in cases of transhumance, made compatible with cultivation rights?
- What is the role for land markets, or land rights markets, in allocating land?
- What is an appropriate role for customary village land rights and allocation systems?
- How can land access and land rights for women be promoted?
- What is an appropriate way to make the transition from collective lands to individually farmed lands?
- At what level of decentralization should land tenure be regulated and administered?
- How can a land tenure regime influence the maintenance of forest cover and protection of soils?

An example of how land rights can affect the environment is found in Panama, which has a regime of titled private property. Forested lands belong to the state and thus by definition cannot become private property. Therefore, in light of the weak enforcement of forest protection provisions, some rural families go into the forest and cut the trees down, and subsequently apply for and gain title because the land is no longer forested and hence no longer the exclusive domain of the state.

The nature of land rights

There are seven basic forms of property rights:

- open access lands (usually rangelands and forests),
- communal lands in customary tenure,
- collective farmlands (state-owned),
- lands owned jointly through cooperatives or other forms of farmer organizations,
- individual rights within associative tenure systems.
- private individual land rights, including ownership, leasing, and rental, and
- state-owned lands apart from collective farms, and lands owned by local governments.

These forms of land tenure can overlap, for example, state lands can be given out in long-term tradable leases. Communal lands can include open access lands and lands ceded to individuals with usufruct rights.

Land rights, including private ownership, are rarely absolute. Restrictions and conditions are usually placed on land rights, and different governmental jurisdictions may control them. Examples of facets of land rights include the following:

- A right to use land and prevent others from using it.
- A right to transmit land to heirs.
- A right to control how land is used (e.g., community zoning restrictions).
- A right to transfer all or part of land use rights to others, at a freely negotiated price.
- A right to derive income from a piece of land.
- Immunity from expropriation.
- Residuary rights that take effect when other rights lapse (e.g., recovering land rented out).
- Contingent rights to land (e.g., claims of a creditor).
- Traditional rights to graze on lands farmed by others, or to drive herds of animals across such lands.
- Rights in perpetuity or rights delimited in time.

Statistical studies have shown that secure land title or secure usufruct rights help promote

- access to credit (India, Thailand, and South Korea),
- investment in the land (Costa Rica and Thailand),
- higher intensity of land use (Jamaica), and
- higher land values (Nicaragua).

Experiences with land reform and land markets

Much of Africa is still involved in the process of formalizing land rights and sometimes transforming them. Colonial land tenure regimes tended to favor small groups of expatriates, and customary village tenure regimes often cannot respond well to all the demands of modern agriculture. They evolved to assure at least a subsistence standard of living to all village members, not necessarily to support a growing and technologically changing agriculture. The question usually is not supplanting

one system with another but rather harmonizing traditional forms of tenure with the clarity, certainty, and long-term security that agricultural development requires. Some of the aims and problems associated with this transition have been noted in the following words in Spore (2004):

> In the past ten years, in an effort to confer a degree of legitimacy and legal status on farmers working the land, many countries in West and Eastern Africa have embarked on land reform or introduced new laws. To varying degrees, all these initiatives have tried to take greater account of existing land tenure systems and to bring modern rights into greater harmony with traditional ones, rather than setting one against the other. But since communities are often not consulted, many of them have proved reluctant to accept such solutions. That has been the case in Ethiopia, Rwanda and Tanzania. Elsewhere, ambitious programs to codify land rights, as in the rural land rights plans in Benin, Burkina Faso and Guinea, have clarified a variety of situations.

Experience has shown that when land rights are formalized, it is important to take measures to ensure that traditional, unwritten rights of small producers are respected. Otherwise, they may lose their access to land to informed outsiders who are better able to navigate modern registry systems. It is also important to ensure that traditional, unwritten secondary rights are respected, such as recognized rights of elderly or handicapped persons to collect harvests from fruit trees, or long-standing verbal land rental arrangements, or grazing rights on fallow cropland.

Some countries now have laws that formally recognize customary, unwritten land rights. These cases include Mozambique, Uganda, Tanzania, and also the 1994 Eritrean land law.

In cases of traditional communal lands, formal group titles to the land may be issued (Honduras). For other traditional lands, a village's right to adjudicate land rights may be formally recognized (Tanzania and Mozambique).

Land registry systems are an important component of security of land tenure. However, they are expensive and slow to develop. Therefore, it can be useful to give recognition to traditional (village) land rights for a possibly very long transition period to 'modern' land registry systems.

For state-owned lands, it is worthwhile to seek tenure systems that give producers stability of usufruct rights, so they will have more incentive to invest in land improvements and manage the land in ways that protect the soils. Trinidad and Guyana, for example, have adopted the model of long-term leases on state lands. These leases are tradable at freely negotiated prices, and therefore they can serve as collateral for bank loans, as well as giving farmers incentives to invest their own funds and labor.

Where there was a legacy of state farms and collective farms, a common approach has been to convert them legally into corporations. In effect, the workers on the farm become its shareholders, and part of their remuneration depends on the financial success of the operation. They can also hire and dismiss managers. Some former collective farms have broken up the land partly into individual titled plots and partly into joint property owned by the new corporation. There are three basic options for transforming a state farm or collective farm: (1) entirely into individual plots, (2) entirely as a corporation, or (3) as an intermediate model with individual plots plus jointly owned assets.

When land has a cost to the user, it tends to be put to more productive uses. This cost can take the form of payments on long-term leases, a purchase price, or payment of short-term rental. However, there is a consensus among land tenure experts that poor farmers in developing countries generally cannot afford to pay a market price for land. For example:

> The cost of acquiring agricultural land in the market often is too high for the poor because investors value the land for reasons other than farming – as insurance, as an investment, as a hedge against inflation, as a tax shelter, or as a means by which to gain access to subsidized credit or public infrastructure such as irrigation works (Binswanger-Mkhize *et al.*, 2009, p. 13).

Expropriative land reform has a checkered history. In some countries, such as Brazil and Guatemala, there have been attempts to establish land funds to offer land mortgages to small farmers at subsidized prices, as a mechanism of land redistribution through markets. The most viable conceptual scheme for such funds is that they operate as second-story institutions, lending through intermediaries, and that purchase prices of land are freely negotiated between private economic agents (or NGOs) and landowners. In this scheme, the fund manages the process to ensure that the purchasing entity is committed to breaking up the acquired land in smaller plots and selling it to poor rural families. This is an example of what Binswanger-Mkhize *et al.* (2009) call the 'willing buyer-willing seller' approach. However, in some cases in which that approach has been applied, the state itself was the buyer, which opens the process to possible corruption in the form of the agreed price of the land. In other cases, mechanisms were not always in place to ensure that the acquired land was sold onward to poor families (at subsidized prices).

Land rental is another valuable mechanism for putting land in the hands of the poor. It enables them to farm while they work toward a purchase or long-term lease. The renting-out option also saves farm families from losing their land during periods of illness.

As noted, women often suffer discrimination in access to land or the ability to become owners or lessees of land. It is important that land laws and inheritance laws and family laws be improved so that women have equal rights to land.

Water Management Policies for Agriculture

Irrigation policy issues and objectives

Water availability and its management are becoming major issues of our times. Many countries in the world are suffering increasing water scarcity. Per capita availability of water is declining by more than 25% per decade in many cases. More than 40 countries now have less than 1000 m^3 of water per capita per year, which signifies serious problems in some parts of a country and in drought years.

Some continents, countries, and parts of countries are much better endowed with water. However, water has low value in relation to weight and hence is expensive to transport. Hence, water scarcity necessarily remains a localized problem. Irrigation is a large part of the water problem. Irrigation

accounts for more than 80% of water use in Africa and approximately 70% worldwide.

When irrigation functions well it is the most powerful way to raise agricultural production and incomes. Some of the most notable examples are the irrigation system of the Office du Niger in Mali, the *fadama* irrigation schemes in Nigeria, the irrigation systems of Andhra Pradesh in India, and many irrigation schemes in the Philippines. However, because of water scarcity, in many countries the emphasis in irrigation is shifting away from finding new sources of water and toward managing demand for water. The strategy varies even by watershed, but in many countries agriculture is being asked to give up freshwater, in favor of other sectors.

Other issues that frequently arise with respect to irrigation include (1) irrigation efficiencies of 50% or less in spite of scarcity of water; (2) the fact that the distribution of water may be unequal among all the users in a system; (3) deficient water control structures which make it difficult to always deliver water in the required volumes and in stable flows; and (4) deterioration of many systems, especially the drainage components. It is also widely observed that farmers tend to apply more water than needed. Together with leaky canals, this implies waste of water; and together with inadequate drains, it leads to soil salinization.

The broad objectives of irrigation policy usually encompass sustainability of the systems and irrigation practices, equity among users, and efficiency in use of water. For irrigation, sustainability tends to mean maintaining water and soil quality, guaranteeing water availability for future generations, financial sustainability for system maintenance, social sustainability (including avoiding public health issues such as breeding diseases in water), and institutional sustainability (who manages the systems).

Frequently groundwater resources are not managed sustainably, and information on their exact quantities is usually lacking. In Jordan, for example, annual groundwater extractions are now 180% of renewable resources, and in Yemen they are 140% of renewable resources, which means rapidly dropping water tables.

The equity objective also has special meanings for irrigation. It can be interpreted to imply emphasis on small irrigation schemes for poor rural families, on participatory methods of designing and operating irrigation systems, and on ensuring that all users have equal access to water allotments. In some circumstances it can also refer to compensation of families displaced by system construction.

In the case of irrigation the efficiency objective usually has the following meanings:

- reducing water losses (technical efficiency),
- increasing net economic returns to users, per unit of water,
- recognizing the economic value of water and allowing transfers to higher value uses in the watershed as necessary, and
- avoiding negative environmental externalities in the watershed (for pastoralists, wildlife, soils, marine life downstream, etc.).

There can be cases of conflicts among the distinct benefits of water, for example, for livestock or crops, for wildlife or crops, for urban or agricultural uses.

International experience suggests the following broad prerequisites for successful irrigation projects: (1) adequate crop prices, (2) secure land usufruct rights, (3) effective technology transfer, (4) credit availability, (5) secure water supplies, and (6) appropriate institutional arrangements and sufficient funding for system maintenance and operation (see the summary of irrigation policies and experiences in Norton (2004), Chapter 5). One of the keys to improving irrigation efficiency is the development of effective water users associations (WUAs).

Irrigation water allocation and pricing

In light of the growing scarcity of water in relation to the demands for it, demand management for irrigation water is becoming as important as developing new water supplies. Broadly speaking, there are five alternative systems of water demand management: administrative allocations of water, user-based allocations (by WUAs), joint decisions on allocations by users and government (as in France and Senegal), market allocation of tradable water rights, and individual allocations (both off-farm and on-farm). Market-based and user-based allocation systems are gaining favor throughout the world. Government allocations are most effective at the intersectoral level and in delivering bulk water to irrigation systems, but not in managing distribution within the systems.

In irrigation the price does not play the normal economic role of balancing supply and demand, except for cases of water markets. The main motives for setting irrigation prices are demand management and cost recovery. With regard to demand management, the main objectives of water pricing are to stimulate water conservation, to encourage allocation of water to higher value uses both within and outside of agriculture, and to minimize environmental problems arising from excessive application of irrigation water on fields.

In the area of cost recovery, the principal aim of water pricing policy usually is to generate enough revenues to cover operation and maintenance (O&M) costs in order to avoid system deterioration and therefore expensive rehabilitation. In some cases the aim also is to recover investment costs, but this requires an even higher price and such a price is rarely applied. Irrigation charges are very low worldwide, often at 20–30% of the O&M costs. There is much evidence that farmers are willing to pay more for water provided the supplies of it are reliable (as in the case of wells operated by farmers).

Note that none of these motives for water pricing requires setting the price equal to the marginal cost of supply, or the price equal to the opportunity cost of water. That happens only under water rights markets and private water systems (e.g., private wells). Typically, a price that recovers O&M costs is well below the opportunity cost of water. However, a price corresponding to O&M cost recovery usually is a practical upper limit to water charges.

Administered prices and prices in water rights markets affect farmers in fundamentally opposed ways. A rise in the former effectively represents a tax on farmers and therefore it lowers their income. A rise in the latter (the market price of water) represents a benefit for farmers because they can sell or lease their rights at a higher price and therefore receive higher income.

Of the many irrigation pricing mechanisms, the most commonly practiced ones are area-based pricing (pricing by the area irrigated), volumetric pricing (pricing by amount of irrigation water), crop-based allocations, tiered pricing by volume, two-part pricing (fixed fee plus volumetric fee), and prices determined by water rights markets (The World Bank, Agriculture and Rural Development Department, 2010, p. 46). Area-based pricing is the most common and the simplest to administer. However, area-based pricing schemes do not include incentives for conservation of water or for allocation of it to higher value uses. Equally, allocations based on crop needs for water do not encourage adoption of less water-intensive crops.

International trends in irrigation water pricing are toward higher water prices, prices levied in volumetric form, application of volumetric prices through bulk sales of water by government to WUAs (to a main canal), WUA decisions on internal pricing (and allocation) within the command area, and increasing reliance on water rights markets.

Policies for managing irrigation systems

In the most common mode of management, government is responsible for maintaining and operating headworks (dams and diversion structures) and larger canals whereas farmers are responsible for water distribution and maintenance along lower-level canals. However, there are a range of options in practice: full government control (Malaysia), government O&M with inputs from users; shared management between government and users; user responsibility for O&M; user ownership of the system but with government regulation; and full control by users (Meinzen-Dick *et al.*, 1997).

Experiences with user-managed systems have been varied but generally positive. It must be recognized that a principal beneficiary of management transfer to users is the government, because it saves the fiscal cost of O&M. However, other common benefits of user management of irrigation include a reduction of O&M costs, greater transparency in cost accounting, timely and more adequate water delivery, better system maintenance, reduction of water losses, more equitable water distribution, and greater flexibility in cropping patterns.

The concept of user responsibility for system management can be extended to user ownership of the system, or user possession of a very long lease, with individuals holding shares in the ownership or in the leasehold. A system in Nepal was developed by issuing 50 shares to 27 households, in proportion to their contributions. Share prices have risen and there have been share transactions among farmers. The higher price has led to water conservation, and thus expansion of irrigated area, and greater system efficiency (Rosegrant *et al.*, 1995).

The international consensus on best practices for organizing WUAs includes the following points:

1. Organize users at the outset and involve them in system design. Bring together community organizers and project engineers. Include all stakeholders, including tenant farmers and women, in the WUA, which should build on preexisting cooperation (social capital).
2. Government should allow users to organize themselves as they wish, with a push to include women. WUAs should be established for drainage and flood control as well as irrigation (this often is a weak point). Devolve as many responsibilities as possible to WUAs (partial devolution is less successful).
3. WUA members should be made fully aware of their rights and responsibilities when the WUA is formed. Clear agreement is needed on the criteria for allocating water in periods of shortage. In larger systems it may be useful to form federations of WUAs (Argentina). Establish mechanisms for conflict resolution.
4. WUA water rights and obligations of the government to deliver water to them should be legally established. Mechanisms for supervision of performance of WUAs should be established. Responsibility for rehabilitation or upgrading before system transfer to users should be established (normally it is on the government's side).
5. Responsibility for system rehabilitation after transfer should be made clear (normally it is on the government's side). In larger systems, WUAs below tertiary gates should not be given control of those gates (in those cases the gates often disappear). Agencies supporting WUAs need a service orientation and accountability.

Water rights markets, informal and formal, exist in a growing number of countries. Such markets have a number of benefits but implementing them is demanding and requires careful planning. The principal benefits of water rights markets are: The potential to sell a water right makes it more valuable and thus provides incentives for water conservation and allocation to higher value uses. Moreover, there is greater flexibility because the rights can be leased out for a season or other short period.

An additional benefit of water rights markets is that (when conveyance structures exist) intersectoral water transfers can occur if needed and yet farmers will receive compensation (payment) for them. This advantage has permitted some cities to avoid the cost of building a new dam by purchasing water rights from farmers (Chile).

In water-scarce Yemen informal water rights and rights markets exist. Owners of tanker trucks purchase water from farmers with wells (or take it from reservoirs without authorization) and sell it to urban households. In various ways the government attempts to compensate villages for drilling wells in their territory for supplying water to cities. Similar experiences have been observed in other countries.

Some of the prerequisites for successful functioning of water rights markets include equitable initial allocations of water rights, effective WUAs, defining water allocation rules for times of scarcity, defining the role of water authorities in enforcing rights and resolving conflicts, and defining procedures for treating return flows and third-party rights.

Women are often left out of decision making regarding the design and operation of irrigation systems, and efforts are needed to overcome this bias. Steps that can be recommended are the following:

1. Before designing a system, carry out gender analysis of the communities, with emphasis on identifying agricultural and water-related tasks that women carry out. Consult women's groups without the presence of men during the design process. Include women in WUAs.

2. Include women in demonstration visits to functioning irrigation systems. Explain fully to men and women what their workloads will be under the system. Consider women's financial situation in establishing water tariffs. Train personnel of water agencies to include women in discussion of irrigation issues.

Watershed and soil management

Watersheds are complex, multifaceted ecosystems, and therefore sound watershed management begins with a thorough assessment of its main characteristics and trends, both natural trends and those caused by human activity. Such assessments are being done or have been done in watersheds throughout Africa.

Examples of the topics covered by a watershed assessment include projected water supply–demand balances, costs of developing new water supplies, projection of water pollution and waste assimilation demands on water supplies, interrelations between groundwater and surface water, upstream–downstream linkages, watershed and ecosystem protection needs, and, in some cases, wastewater treatment options. The most basic tool, water balances by month or season, usually does not exist.

Other topics frequently covered in a watershed assessment include the efficiency of existing irrigation systems, the possibilities of water conservation in each use, trends in water quality, likely directions and magnitudes of future intersectoral water transfers, and social issues accompanying water projects (e.g., public health issues related to water, resettlement of populations for dams, and changes in water supplies for pastoralists).

The importance of a careful diagnosis of the issues in a watershed arises from the fact that, according to the World Agroforestry Center, on 10% of the land one can do or control 90% of the damage to streams and rivers. For designing interventions on that 10% of the land, the participation of local communities has been found to be a crucial element:

> User participation is increasingly being recognized as critical for success in watershed development and management projects… Empirical evidence suggests that giving users a role in managing their own watershed resources can lead to projects that are more efficient and effective than their top down predecessors (Johnson *et al.*, 2001, p. 20).

The central role of local participation in watershed management has led to a movement away from strictly physical definitions of watershed boundaries:

> Field experience has led the Project to address watersheds more as geopolitical territories (defined on the basis of their governance and social dimensions) than as hydrological units (as in conventional watershed management initiatives). This shift from a 'hydraulic' to a 'territorial' approach required that the scope of watershed management has to be redefined… (FAO, 2003).

The importance of participation has been emphasized in the African context as well as generally:

> There is more to sound water management than simply saving it. Equal and careful – read sustainable – distribution and use of water requires the initiative and ongoing involvement of stakeholders. It is a permanent process since every solution, every innovation leads to a new challenge. If a community creates a small dam for watering cattle, the resulting unprecedented body of water makes the whole community brim with ideas… This will require new rounds of consensus within the community and with others, upstream and downstream. It requires, too, an explicit say in it by women (Spore, 2001).

Improved watershed management can reduce loss of soils through erosion, but another major threat to soils is loss of nutrients. This trend poses a threat to the long-run capacity to produce food. It occurs because of inappropriate fertilization and because crop residues are not left on the fields. The nutrient issue has been summarized in the following words:

> All African countries, except Mauritius, Reunion and Libya, show negative nutrient balances every year… In the semiarid, arid and Sudano-Sahelian areas that are more densely populated, soils lose 60–100 kg of nitrogen, phosphorus, and potassium (NPK) per hectare each year. The soils of these areas are shallow, highly weathered, and subject to intensive cultivation but with low levels of fertilizer application. Limited water availability and intensified land use due to increasing population size have restricted crop diversification and the adoption of proper management practices. Short growing seasons contribute to additional pressure on the land (Henao and Baanante, 1999).

A precondition for the adoption of soil conservation practices is secure long-term tenure rights to the land. A study of this issue in Benin came to the following conclusion:

> The willingness to invest in the long run is significantly higher on owner-operated fields than on leased, borrowed or pledged fields with only medium or short-term use rights. This is particularly evident in the incidence of tree planting. In this survey, landowners planted more than 200 trees per hectare on average, while the number of trees per hectare on non owner-operated fields with medium and short-term use rights were only 26 and 6.3 respectively… (Neef, 2000, p. 126).

Similar results have been found in a study for small-scale hillside farmers in Honduras. That study concluded, "We found... that ownership of the land is positively associated with the use of soil conservation practices" (Jansen *et al.*, 2003).

Whether the land use rights take the form of long-term usufruct or ownership, the conclusions about the effect of tenure security on soil conservation appear to be quite general. For Eritrea, it has been observed that

> A [tenure] rotation period of 5–7 years is too short for people to have the incentive to make long-term investments in improving the land, such as tree planting, digging water wells, making water canals and soil conservation structures, etc. (Negassi *et al.*, 2000, p. 1).

For these reasons, a sound watershed management plan is vital for agricultural productivity and sustainability, and policy needs to find ways to promote it, in the social, economic, and ecological context of each watershed.

Rural Financial Policies

Most developing countries have struggled with agricultural finance without finding an entirely satisfactory solution. In particular the lack of medium-term finance for activities such as irrigation, livestock investments, and planting tree crops remains a major hurdle in developing countries, and sometimes even export finance is difficult or impossible to obtain.

The reluctance of large commercial banks to lend to agriculture is widespread, especially if they have secure alternatives to invest in such as urban real estate development and government bonds. Many countries have created state agricultural development banks but on the whole their record has been mixed, as governmental agencies often do not possess capabilities as financial managers.

Microfinance has proven to be a viable and rapidly expanding approach in many countries, but often its lending is short term and is more oriented toward urban populations and rural marketing activities. It can be as valuable to work to build capacity in local financial intermediaries such as savings and loan cooperatives. The potential for mobilizing rural savings through the farmers' organizations is enormous. The success of rural banking sector in Kenya and Namibia, for example, speak volumes for this possibility. Rural banking in Kenya and Koshi y'O Muti (Savings Under the Tree) in Namibia, and Badan Kredit Kecamatan in Indonesia, are some of the success stories besides the Grameen Bank and a development NGO, formerly the Bangladesh Rural Advancement Committee in Bangladesh. The discipline generated from these systems has resulted in repayment rates of up to 98%. Rural savings and credit cooperatives have worked elsewhere in stimulating agricultural and other socioeconomic growth, although they may be exposed to a high level of risk because of geographical concentration and sometimes a concentration in a few agricultural products (forms of covariance risk). Adding consumer lending to their portfolio can help reduce the risk, as can an apex organization that manages liquidity to these institutions in multiple geographical areas.

Another option that has proven useful in some countries is the creation of a loan guarantee fund (including for agroexports) or a second-story rediscount line that provides funds to financial intermediaries for on-lending to agriculture or other strategic sectors (Wenner, 2001). Usually, the interest rate charged to the intermediaries is made sufficiently attractive to encourage them to participate in the program, but sometimes these rediscount lines are not fully utilized. A common reason is that banks may already be at their lending limit, as a ratio to capital, in more secure kinds of investments. Neither of these approaches is sustainable over the long run because they require a continuing source of subsidy (i.e., the national treasury).

A consensus has emerged that interest rate ceilings, though still prevalent, are inimical to development of financial institutions, especially for agriculture where financial risks may be higher. For most farmers, the main concern is access to credit, more than its cost, because without access to financial institutions they may pay extremely high interest rates on the informal lending market. Equally, it has been found that holding interest rates on government agricultural loans at artificially low levels is counterproductive. It discourages financial institutions from lending to the sector, and it also tends to encourage allocations of investment funds to less productive uses. When lending rates become negative in real terms, financial institutions see their capital and deposit base eroded over time, with the result of decreasing amounts of loanable funds available in real terms. In addition, low lending rates mean low deposit rates that discourage mobilization of financial savings. One of the lessons of rural finance experience is that farming families need a range of financial services, and not only loans. They need opportunities to make deposits, as their income comes at irregular intervals, and they require facilities such as mechanisms for transfer of funds (these and other conclusions from international experiences are reported in many studies; one of the classic references is Yaron *et al.* (1997)).

Crop insurance schemes have been implemented in an increasing number of developing countries. An issue has been the cost of administering them but a useful approach has been developed in the form of basing indemnity payment decisions on detailed meteorological data by zone and following up with field checks only for outliers with greater damage (two useful references are Herbold (2010) and Roberts (2005)). Other forms of crop insurance include coverage against substandard yields and revenues, and against specific types of damage. The latter is used for livestock.

The nature of collateral has received attention in reviews of financial systems. The consensus is that moves to make land tenure more secure, whether by ownership or leasehold, can improve farmers' access to finance. In addition, legislation is being introduced to widen the kinds of moveable collateral, including invoices and crops in storage (Yaron *et al.* 1997; Fleisig, 1995). Village banks and microfinance entities make effective use of social collateral, in the form of group guarantees. Developing value chain finance can require legislation for these and other forms of collateral, and policy tools to make them available include legislation for and implementation of a program of warehouse receipts (certificates of grain deposit) that gives access to finance based on grain stored in approved facilities, and regulations that facilitate the use of invoices for agroinputs and agricultural sales as collateral (factoring). Input suppliers and agricultural marketing agents are significant sources of agricultural finance, and regulations of this nature contribute to increasing the flow of finance and lowering its cost to borrowers. A common form of value chain finance is the buyer-driven model or triangular finance, in which the buyer repays the production loan on receipt of the harvested commodities (Miller, 2013). In this case, the risk is shared between the bank and the product buyer, because of the possibility that the producer may not deliver the commodities, or may do so in insufficient quantities.

The need for venture capital for agricultural enterprise startups is beginning to be recognized (with the support of the International Finance Corporation, a member of the World Bank group, Mozambique has set up a risk capital fund for small and medium enterprises, and Uganda has venture capital programs for agriculture. Panama's Impulso Panamá program has been an example of this kind of fund). Governments can provide this kind of risk capital, preferably with independent panels to select qualifying enterprises. This will generate shareholdings in the enterprises for the government,

and regulations should establish a deadline (perhaps 5–7 years) at which the government would be obliged to sell the shares, giving first rights of purchase to the enterprise concerned (at the initial valuation). Absent a purchase from the enterprise, the shares would be sold at auction. The entrepreneurs would be required to contribute a specified percentage of the capital. Experience has shown that lack of this form of financing is a significant gap in capital markets, and banks typically are not interested in financing enterprises that involve new products or new technologies, for lack of ability to appraise such projects. Although this kind of finance may not be directly aimed at the rural poor, it can improve their incomes significantly by supporting the development of outlets for their higher value products and enterprises that will provide them employment and technical assistance on issues like quality control. Increasingly, these innovation funds require collaboration among the actors in the value chain (Rajalahti and Larson, 2011).

Another financial policy topic that has been explored more recently is the question of the nature of bank supervision and regulation. Worldwide, it was designed for the purposes of providing adequate supervision to commercial banks, but for that reason it has been found to be inapplicable to microfinance and, increasingly, to agricultural finance. (Fiebig (2001) was one of the first to emphasize the different nature of regulatory requirements for agricultural loan portfolios). Collateral often is informal in microfinance, and in agriculture loan classification, reporting requirements and risk provisioning have to be different, among other issues. Weekly or monthly loan reporting is not feasible for crop loans under which repayment will be lump sum and will take place at harvest time, months after the loan is placed. A number of countries have created a special regulatory window in the Superintendency of Banks for microfinance institutions that wish to take in deposits. However, the need for a special regulatory regime for agricultural lending is only beginning to be recognized.

These findings have led to considerable ferment in developing countries in regard to agricultural and rural financial systems. The development of microfinance is the foremost thrust, but collateral legislation, crop and livestock insurance schemes, venture capital windows, systems of village banks, supervisory requirements, and interest rate regulations are also undergoing development or change. Equally, the role of the state in the financial sector is being reviewed. It is now clear that executive branches of governments are not as well suited as the private sector to provide and manage loans directly, but nonetheless they have a vital role in providing incentives and resources to the financial system, as well as establishing an appropriate regulatory and legislative framework.

In summary, priorities for rural financial policies in developing countries include the following:

- Improve access to credit and other financial services by strengthening the rural financial system with emphasis on enhancing its sustainability.
- Widen the range of types of collateral and financial instruments, including crop insurance, available to the rural population.
- Develop mechanisms such as venture capital funds, guarantee funds, and rediscount lines in order to increase the amount of investment finance available with emphasis on the kinds of productive investments not well covered by existing financial markets.
- Strengthen the demand side for rural financial services through activities to improve financial literacy in rural areas and the capacity of local financial intermediaries.

Policies for Agricultural Technology

Issues concerning agricultural technology systems

Agricultural technology classically embraces research and extension, and for the most part research in developing countries has meant development of new crop varieties and improved methods of crop management in the field. The vision of research and extension systems has been broadened to encompass agricultural knowledge and information systems (AKIS). Research and extension systems have had a number of notable successes, going back to the Green Revolution, but nevertheless several important issues have arisen (Norton, 2004, Chapter 8; Suvedi and McNamara, 2012; and the other publications of the project for Modernizing Extension and Advisory Systems (MEAS), headed by Paul McNamara at the University of Illinois). Some of them are as follows:

- Although many studies have confirmed the very high economic rates of return to agricultural research, funding for it is almost invariably insufficient, and one of the consequences is weak sustainability of many lines of research.
- The sources of agricultural research are often limited to one governmental agency and hence the benefits of tapping into diverse approaches are not realized.
- The priorities in a national agricultural research agenda are often set by research scientists and they may not reflect the needs and priorities of farmers.
- In relation to this issue, research rarely concentrates on high-value crops, instead staying with staple crops, and it almost never extends to technologies for postharvest handling, processing, and packaging.
- Farmers can inform the research process about problems that need to be addressed and also can contribute knowledge to the process from their own experiences. Hence, there is a need to find avenues for greater involvement of farmers in research (one of the early, successful efforts along these lines was the creation by the International Center for Tropical Agriculture (CIAT) in Colombia of the approach of Local Agricultural Research Committees, which has spread to other countries (Ashby *et al.*, 2000)).
- There is a need to orient more research toward the needs of women farmers.
- The institutional incentives for government extension workers are to satisfy the requirements of their institution and not necessarily to address the problems faced by farmers.
- Traditionally extension systems have operated in a top-down manner, delivering messages from researchers to farmers, rather than operating as facilitators in farmers' search for relevant knowledge. The top–down approach is poorly suited to the heterogeneous farming conditions of smallholders in most developing countries.

- Traditionally extension systems have not responded well to the needs of women farmers.
- A one-size-fits-all approach does not fulfill the extension needs in developing countries; rather, the trend is toward pluralistic systems with multiple providers.

Owing to these weaknesses in research and extension systems, the private sector and NGOs have increasingly become involved in those efforts. Moreover, because of the importance of these issues, governmental policies for technology systems are undergoing evolution in many parts of the world.

Policy frameworks for agricultural technology systems

In response to these increasingly urgent issues, policies for agricultural technology systems have been experiencing important changes. Some of the most relevant new policy orientations are the following:

- Some countries have set up competitive mechanisms for awarding research contracts. Funds are awarded on the basis of the quality and relevance of proposals, and typically the national agricultural research agency is eligible to submit proposals as well. In some cases (as in the program of the Panamanian National Secretariat for Science, Technology and Innovation (SENACYT)), proposals can include the fields of postharvest management and agroprocessing.
- Following the examples of CIAT and efforts in Africa, programs are now put in place to carry out selected research activities on farmers' plots, with the participation of farmers.
- Some programs are put in place to attract private investment into adaptive research for high-value products (Rwanda).
- In some cases, reviews of the priorities of women farmers are used as an input into the research agenda.
- To correct the institutional incentives issue for agricultural extension, in some cases the contracting of farm advisors is delegated to farm cooperatives and associations, even though governments may continue to fund all or part of the advisory services via reimbursements of those agencies. This ensures that the advisors address the priorities of those farmer groups.
- Approaches like the Farm Field Schools have been implemented, in which farmers participate in the search for improved cultivation methods and become trainers to work in participatory ways with neighboring farmers.
- More women extension agents and farm advisors are being recruited, and extension services direct some of their activities exclusively to women farmers.

Glossary

Broiler birds Birds bred and raised for meat production.
Gamonts A developmental stage within the life cycle of Eimerian species parasites. Specifically, gamonts are the parasitic forms that occur during the sexual phase of the life cycle, which lead to the formation of oocysts that are spread throughout the feces.
Hazard analysis and critical control point (HACCP) A management system in which food safety is addressed through the analysis and control of biological, chemical, and physical hazards from raw material production, procurement, and handling to manufacturing, distribution, and consumption of the finished product.
Impaction Accumulation of eggs and egg material within the oviduct and is usually a consequence of dystocia, metritis, or salpingitis.
Layer birds Birds bred and raised to lay eggs.
Necrosis Refers to the process when a living cell dies due to irreversible injuries.
Notifiable diseases Diseases that must be immediately reported to health and agriculture authorities.
Oophoritis An inflammation of the ovaries that is mainly caused by bacterial agents, such as *Escherichia coli* (*E. coli*).
Pathognomonic A term used to denominate the characteristic clinical signs or lesions of a particular disease or condition.
Poultry Birds used for the purpose of production, which include mainly chickens and turkeys; however, according to the region, ducks, geese, partridges, quails, and ostriches are also used.

Poultry Production: Economical Perspective and Public Health Impact of Diseases

The demand of poultry products has increased parallel to the continual rise in the human population. This can possibly be explained as poultry meat and eggs represent an efficient source of protein and have low cost of production in comparison with other sources of protein, such as pork and beef (Service, 2013). Nowadays almost every world region (Africa, North and Central America, South America, Asia, Europe, and Oceania) has to improve their production systems to accomplish the global demand of richer and more nutritional diets. Besides, global trading of poultry products has also increased, especially between the major producers (i.e., the United States, Brazil, and China) and the rest of the world (Stenhouse, 2008).

All infectious agents, toxics, and nutritional imbalances have an impact on the performance of the farm and consequently on the local poultry industry. Additionally, some diseases of birds, such as influenza virus, imply a potential zoonotic risk to the population and the notification of some strains related to high virulence involves commercial restrictions (ban on poultry imports/exports) and therefore reduce profitability (Yin *et al.*, 2013). Therefore, the goals of any production system (conventional or sustainable) will always be to prevent the risk and consequences of diseases.

Sustainable Production Systems in Poultry

Sustainable or organic production systems consist of a series of strategies developed to decrease the environmental footprint to a minimum in the process of production. In poultry farms, the environmental pollution is generated during the process of growing animals, producing feed, generating manure, and obtaining housing accessories (litter materials and heating devices). Therefore, these systems have to implement measurements at the level of housing, lighting, fencing, and adequate feeder and waterer designs as well as management of litter, composting, and land (Xin *et al.*, 2011).

These organic farming systems consist of several types of production methods that invariably allow access to pastures and involve less density of birds per square meter (Castellini *et al.*, 2006), implying improvements that maximize animal welfare (Beaumont *et al.*, 2010). Examples of these types of sustainable production systems include the following: free range, pastured poultry, semi-intensive, and others (Fanatico, 2007). An important point for the promoters of these systems is the search of alternatives to medication, and especially to antibiotics, which could reduce the emergence of antibiotic-resistant strains of bacteria in the birds themselves or/and the presence of residues in meat and eggs that induce resistance to infected humans (Fanatico, 2008).

Although sustainable and conventional production systems require completely different management strategies, their success depends on the establishment of adequate preventive and control measures to reduce the detrimental effects of diseases in the flock.

Basic Understanding of Disease, Prevention, and Control

Disease may be defined as an impairment of normal physiological function that reflects some structural or functional alteration in the cells or organisms (Slauson and Cooper, 2002). These may be caused by a single factor or more commonly by a combination of different factors. Multifactorial diseases are

 doi:10.1016/B978-0-444-52512-3.00183-2

more difficult to diagnose and sometimes require an epidemiological approach. This approach allows assessing all possible etiological agents and associated risk factors, selecting the most adequate laboratory tests to determine the cause of the disease. It is also important to take the intrinsic factors (such as species, breed or strain, immune status, and age of bird) into consideration that can determine the presence of a disease (Sjaak de Wit, 2008).

Prevention and control of disease require a careful evaluation of the entire farm and establishment of a series of biosecurity measures that allow assessing the possible challenges and their impact on the production system. Once established, all factors determining disease can be better recognized and corrected. In general, the recommended approach is to perform a risk assessment and establish the Hazard analysis and critical control point (HACCP) principles on the poultry farm, determining the points where potential hazards could occur and biosecurity measures have to be implemented (Collett, 2013). Biosecurity involves measures at the level of environmental control and management, including elaboration of vaccination and medication programs and also application of effective cleansers, sanitizer, and disinfectants. These biosecurity measures are essential to control the diseases and reduce their economic and public health significance (Lister, 2008).

In summary, prevention and control of diseases depend in part on the ability to recognize the clinical signs, lesions, and all possible etiological agents related to them. For this reason, in the following section on poultry and avian diseases, emphasis was given to the identification of the agent, mechanism of disease, and lesions observed in the affected birds.

Viral Diseases

Influenza Virus

Influenza viruses are segmented negative-stranded ribonucleic acid (RNA) viruses belonging to the family Orthomyxoviridae. Avian influenza viruses are divided according to their virulence in highly pathogenic avian influenza virus (HPAIV) and low-pathogenic avian influenza virus (LPAIV). Influenza viruses are also classified on the basis of the nucleocapsid and matrix proteins into three types (A, B, and C), but especially type A genera cause disease in birds. In addition, influenza A viruses (IAVs) may further be classified into subtypes according to 16 hemagglutinin (H) and 9 neuraminidase (N) antigens. Only the IAVs belonging to the H5 and H7 subtypes are notifiable to health authorities, because they are frequently involved in HPAIV outbreaks and almost all zoonotic viruses have been from these subtypes (OIE, 2013a).

The most susceptible species to infection are gallinaceous species, such as chicken and turkeys (Perkins and Swayne, 2003). Wild birds are the main reservoir of IAVs and disseminated the virus directly to the poultry farms. Birds are infected mainly through the fecal–oral route, although the virus can also be transported mechanically (Prosser *et al.*, 2013).

Clinical forms depend on the virulence of each IAV. LPAIVs are associated with suppurative pneumonia, sinusitis, kidney lesions, and occasionally pancreatitis. However, the HPAIVs cause hemorrhagic and necrotic lesions in different visceral organs, such as the heart, pancreas, and adrenal gland (**Figure 1**; Swayne *et al.*, 2013).

Newcastle and Other Paramyxoviruses

Newcastle disease virus (NDV) is a nonsegmented, negative sense, single-stranded RNA virus of the family Paramixoviridae and genus *Avulavirus*. Specifically, Newcastle disease is caused by serotype 1 viruses (APMV-1) (King *et al.*, 2012c).

NDV induces different clinical conditions with variable severities or pathotypes. These pathotypes include the following: viscerotropic velogenic NDVs (induce hemorrhagic lesions in the intestinal tract), neurotropic velogenic NDVs (produce high mortality and respiratory and nervous signs), mesogenic NDVs (induce respiratory signs with low mortality), lentogenic respiratory NDVs (cause slight respiratory signs), and asymptomatic enteric NDVs (induce an unapparent enteric infection). In the field, these are usually overlapped between pathotypes and exacerbation by secondary pathogens (Alexander, 2008).

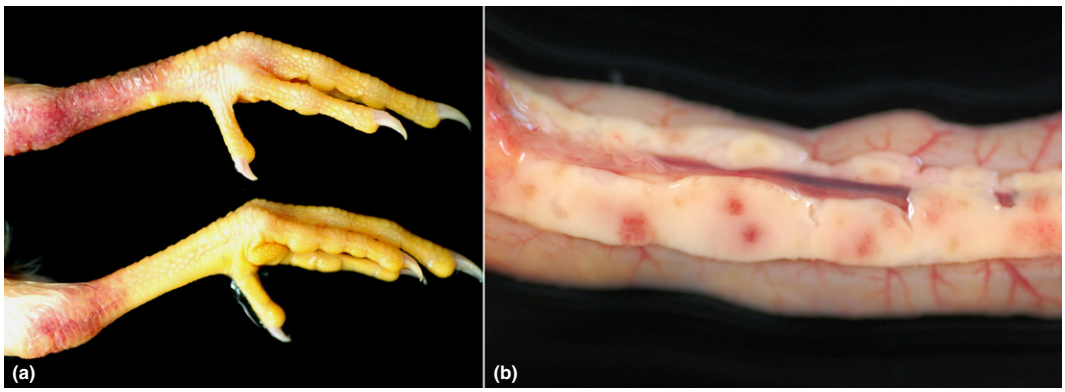

Figure 1 Gross lesions caused by HPAIV H7N1 in specific pathogen free (SPF) chickens. (a) Severe subcutaneous hemorrhages around the hock joint and shank of birds. (b) Multifocal petechial hemorrhages and necrosis in the pancreas of chickens intranasally inoculated with HPAIV A/chicken/5093/99 (H7N1), 5 days postinfection. Photos provided by Natàlia Majó i Masferrer, SDPV (Servicio de Diagnóstico de Patología Veterinaria)-CReSA (Centre de Reserca en Sanitat Animal, Barcelona).

Approximately 250 species of birds can be infected by NDV, through fecal-oral or respiratory route of infection, according to the clinical presentation. Wild birds are the main reservoir of NDVs. As mentioned previously, the lesions are variable; viruses causing respiratory disease produce hemorrhages in the trachea, whereas the enteric viruses cause hemorrhages in the intestinal tract, particularly in the proventriculus (Miller and Koch, 2013).

NDV is zoonotic and has been reported in people with eye infections who are involved in activities related to NDV diagnosis and in poultry production (Conan *et al.*, 2012).

Poxvirus

Fowlpox virus (FWPV) is caused by an *Avipoxvirus* that contains a double-stranded DNA genome and replicates in the cytoplasm of the cells. Poxvirus infections have been recognized in 230 species of birds (Gyuranecz *et al.*, 2013). *Avipoxvirus* is a large virus that contrary to most of the virus is not filterable and consequently the viral particles could be visualized by light microscopy (inclusion bodies containing elementary particles). *Avipoxvirus* is highly host specific; therefore, infection with one type of poxvirus does not protect against others. In fact, poxviruses are named according to the susceptible host species (i.e., Fowlpox virus, Canarypox virus, Pigeonpox virus, Psittacinepox virus, Turkeypox virus, etc.) (Tripathy and Reed, 2013).

Avipoxvirus is transmitted by means of desquamation of skin lesions or by the biting of insects that sting the unfeathered skin areas, producing the characteristic papular, vesicular, and crusty lesions visible in the nares, eyelids, and legs. Birds can also ingest or inhale viral particles, producing diphtheritic lesions in the oral cavity, pharynx, larynx, and trachea (Tripathy and Reed, 2013).

Avian Encephalomyelitis Virus

Avian encephalomyelitis is produced by a nonenveloped, icosahedral, single-stranded RNA virus of the family Picornaviridae (Todd *et al.*, 1999). The disease affects mainly chickens and occasionally turkeys, pheasants, Japanese quail, and pigeons. Clinical signs include reduction in hatchability and nervous signs in young birds, whereas adult birds show enteric signs. Gross lesions are frequently unapparent. Microscopic changes are considered pathognomonic and include diffuse gliosis and central neuronal chromatolysis in the brainstem and midbrain, as well as presence of gliosis in the molecular layer of the cerebellum. Additionally, lymphoid perivascular aggregates are seen through the central nervous system as well as in the dorsal root ganglia, proventriculus, gizzard, pancreas, and other viscera.

Other Picornaviridae family viruses causing serious diseases in birds include the following: Duck hepatitis virus (causes hemorrhagic lesions and necrosis in the liver of duck) and Turkey viral hepatitis (induce similar lesions in turkeys) (Suarez, 2013).

Infectious Bursal Disease

Infectious bursal disease (IBD) virus is a pathology to chickens and is caused by a nonenveloped, double-stranded RNA virus, that is member of the Birnaviridae family (Muller *et al.*, 1979). The viruses causing IBD are divided into two serotypes (serotypes 1 and 2), but only viruses of the serotype 1 infect B cells. The high mutational rate of IBD viruses induces high genetic diversity and continual emergence of more virulent forms, which are able to overcome the previous acquired immunity and persists in the population, such as the European very virulent viruses (vvIBDV) (Maas *et al.*, 2001).

The main target organ of IBDV is the bursa of Fabricius, where the virus causes lymphocytolisis and persists within the macrophages. Chickens with a well-developed bursa of Fabricius (between 3 and 6 weeks of age) are most susceptible. Gross lesions consist of petechial hemorrhages in the leg and thigh muscles, swelling of the bursa of Fabricius and petechiae, and sometimes petechiae in the mucosa of the proventriculus. Besides, there may be splenomegaly, swelling of the liver, and nephrosis (Eterradossi and Saif, 2013).

Reovirus

Reovirus corresponds to a nonenveloped virus that contains ten segment of double-stranded RNA. Reovirus causes arthritis and tenosynovitis in domestic fowl (De Gussem *et al.*, 2010), but it also has been associated with a multisystemic disease in African gray parrots (Sánchez-Cordón *et al.*, 2002). In addition, Reoviruses have been detected in budgerigars, black-tailed gulls, pheasants, bobwhite quail, pigeons, and mallard duck; however, only in a few cases they have been related with disease (Jones, 2013). Lesions commonly found (especially in broiler chickens) consist of tenosynotivis and arthritis, affecting the hock joints and rupture of the gastrocnemius tendon in chronic cases. Reovirus has been also related with ulcerative enteritis, acute and chronic respiratory disease, pericarditis, hydropericardium, anemia, acute hepatitis, inclusion body hepatitis, malabsorption syndrome in broilers, and poult enteritis and mortality syndrome (PEMS) in turkeys (Jones, 2013).

Rotavirus

Rotavirus also belongs to the family Reoviridae, and its genome contains 11 segments of double-stranded RNA. Rotaviruses have been detected in chickens, turkeys, pheasant, partridges, ducks, guinea fowl, ratites, pigeons, and parrots. In these species, Rotavirus may cause subclinical infections (predominantly in chickens and turkeys) and malabsorption and secretory diarrhea of different severity. The target cells of Rotavirus are the mature villous epithelial cells of the small intestine, causing villous atrophy (Day, 2013).

Circovirus

The family Circoviridae contains nonenveloped, icosahedral viruses with single-stranded circular DNA genomes. This family includes the genus *Gyrovirus*, which is represented by Chicken anemia virus (CAV), and the genus *Circovirus*, which contains Psittacine beak and feather disease virus (BFDV), Pigeon circovirus (PiCV), Canary circovirus (CaCV), and Duck circovirus (King *et al.*, 2012b).

CAV infects only domestic fowl and does not have zoonotic potential. Clinical signs are observed in the progeny of breeder flocks that are infected for the first time (vertical transmission) and that are susceptible (i.e., chickens without maternal antibodies). In these birds, CAV causes anemia, aplasia of the bone marrow, and atrophy of the thymus, spleen, and bursa of Fabricius (Santen *et al.*, 2004).

Adenovirus

Adenoviruses are nonenveloped double-stranded DNA viruses that replicate in the nucleus of the cell, producing inclusion bodies. The family Adenoviridae includes four genera, but only three of them (*Avidenovirus*, *Siadenovirus*, and *Atadenovirus*) are related to diseases in birds (King *et al.*, 2012a).

The *Aviadenovirus* of domestic fowl has been associated with several conditions that include the following: inclusion body hepatitis (IBH), hydropericardium syndrome, respiratory disease, tenosynovitis, diarrhea, drop in egg production, and poor performance (Hess, 2013).

The *Siadenoviruses* are represented by the Turkey Adenovirus A, which causes sudden death consequence of severe hemorrhagic enteritis (Pierson and Fitzgerald, 2013).

Egg drop syndrome is induced by an *Atadenovirus* that replicates primarily in lymphoid tissues and massively in the pouch shell gland region of the oviduct, producing eggshell changes (loss of shell pigmentation, thin and soft shells, and shell-less eggs) (Smyth, 2013).

Parvovirus

Parvovirus is a single-stranded DNA virus. In birds there are two important diseases caused by viruses of this genus: Derzsy's disease cause by Goose parvovirus (GPV) and Muscovy duck parvovirus. GPV affects young gosling and Muscovy ducks and is also known as gosling plague, goose hepatitis, enteritis, or infectious myocarditis. GPV causes a multisystemic disease, which is characterized by the induction of Cowdry type A intranuclear inclusions in myocardial cells, enterocytes, and smooth muscle cells (Glávits *et al.*, 2005).

Infectious Bronchitis Virus

The avian infectious bronchitis virus is a positive-sense, linear, single-stranded RNA virus of the family Coronaviridae and genera *Coronavirus* (Jackwood, 2012). Avian coronavirus causes respiratory signs and renal damage in broilers as well as drop in egg production in laying hens. Gross lesions consist of catarrhal exudate in the nasal cavity, sinuses, and trachea, sometimes affecting the low respiratory tract. Some IBV strains cause interstitial nephritis and visceral gout. Recently, there have been reports of IBV strains that affect the development of the reproductive tract, inducing the 'blind or false layers,' consequence of agenesia or hypoplasia of the oviduct (Cook *et al.*, 2012).

Infectious Laryngotracheitis Virus

Infectious laryngotracheitis is a respiratory disease of domestic fowl that is caused by Gallid herpesvirus 1 (Iltovirus: ILT-like virus) (King *et al.*, 2012a). The disease is observed mainly in young male birds of heavy breeds between 3 and 9 months of age. The virus can remain in the trigeminal ganglia of birds latently infected, which begin to intermittently reexcrete the virus on stress conditions (Williams *et al.*, 1992).

The clinical presentation is restricted to the upper respiratory tract and can be peracute, acute, mild, or asymptomatic. In the peracute form, birds are found dead without prodromal signs due the induction of necrosis and hemorrhagic tracheitis. Acutely affected birds show caseous diphtheric exudates and hemorrhages in the trachea, which obstruct the respiratory pathways. In mild forms, there are mucous and caseous exudates in the trachea, and histologically it is possible to see pathognomonic Cowdry type A intranuclear inclusion bodies and multinucleate cells (syncytia) in respiratory and conjunctival epithelial cells.

Other important member within the Herpesviridae family is the Anatid herpesvirus 1 that causes Duck enteritis virus or Duck Plague (García *et al.*, 2013).

Arhtropod-Borne Viruses

Within this group are included the arboviruses (arthropod borne), which are viruses transmitted by hematophagus arthropods to vertebrate hosts. This group includes 535 viruses. Among these, six families of viruses have been isolated in birds and ornithophilic arthropods: Togaviridae, Arenaviridae, Flaviviridae, Bunyaviridae, Reoviridae, and Rhabdoviridae (Capua, 2008).

Highlands J virus

Highlands J virus (HJV) causes disease in Chukar Partridges and turkeys. HJV corresponds to an *Alphavirus* of the Togaviridae family. HJV causes ovarian atrophy and mortality in young poults (Ficken *et al.*, 1993) and encephalitis and myocarditis in Chukar Partridges (Eleazer and Hill, 1994).

Easter equine encephalitis virus

Easter equine encephalitis virus (EEEV) infects birds and humans and has been reported in North and South America. EEEV is transmitted by a highly ornithophilic mosquito (*Culiseta melanura*), which feeds mainly from passerine birds (Hassan *et al.*, 2003) EEEV causes encephalitis and occasionally myocarditis in pheasants, turkeys, ducks, Chukar Partridges, and chickens (Guy, 2013).

Western equine encephalitis virus

Western equine encephalitis virus (WEEV) also infects humans and other mammalian host, besides birds. WEEV is found in the Americas and is transmitted by ornithophilic mosquitoes of the *Culex* genus. WEEV has been isolated from pheasants, turkeys, and Chukar Partridges. In Chukar Partridges, WEEV has been related to high mortality (Guy, 2013).

Venezuela equine encephalitis virus

Venezuela equine encephalitis virus infects more than 100 species of birds and is transmitted among them by mosquitoes belonging to the genus *Culex* (Capua, 2008).

West Nile virus

West Nile virus (WNV) belongs to the Flaviviridae family and its presence has been described in Africa, Asia, Europe, and North America. The virus can be transmitted by at least 43 mosquito species from 11 genera. WNV infects birds, reptiles, amphibians, mammals, mosquitoes, and ticks; however, birds are the main reservoir. Infection has been detected in geese, ducks, Chukar Partridges, pheasants, and a wide variety of feral and captive birds (Himsworth *et al.*, 2009). Some WNV strains present in North America and the Middle East have evolved to become more virulent (Isr98), causing meningoencephalitis, myocarditis, and splenomegaly in humans (Guy, 2013).

Crimean–Congo hemorrhagic fever virus

Crimean–Congo hemorrhagic fever virus (CCHFV) is an *Arbovirus* transmitted by ticks that infects birds and causes disease in humans. CCHFV is found in Asia, Africa, the Middle East, and Eastern Europe and in the European Union. CCHFV have been reported in ostriches, chickens, and guinea fowl, but it does not cause clinical signs (Bente *et al.*, 2013).

Marek's Disease

Marek's disease (MD) is a lymphoproliferative and neuropathic disease of chickens, and occasionally turkeys, quails, and geese. This disease is caused by a cell-associated lymphotropic herpesvirus of the genus *Mardivirus*. The genus *Mardivirus* contains three serotypes, but MD is induced only by viruses of serotype 1. Viruses within this serotype show variable pathogenicity, which are subdivided into different groups: mild (mMDV), virulent (vMDV), very virulent (vvMDV), and very virulent+ (vv+MDV) (Witter, 1998).

Transmission occurs through direct and indirect routes (airborne route). The virus replicates in keratinizing epithelia cells of the feather follicle, so the desquamated cells and feathers serve as a source of infection (Jarosinski, 2012).

There are different clinical forms of the diseases that include the following: the classical form, acute form, acute cytolytic form, and transient paralysis syndrome. The classical form involves neural lesions that cause partial or complete paralysis of the legs and wings, torticollis, and paralysis. The acute form is characterized by the induction of lymphomas in visceral organs. The acute cytolitic form is caused by vvMDV strains, which produce severe atrophy of the lymphoid organs and high mortality in birds between 10 and 14 weeks of age. Transient paralysis occurs in birds between 5 and 18 weeks of age and consists of vasculitis and edema that induce flaccid paralysis (Schat and Nair, 2013).

Avian Leukosis, Reticuloendotheliosis, and Other Lymphoproliferative Diseases

The retroviruses are RNA viruses that cause neoplastic cells transformation and tumor development. Retroviruses affecting birds include the following: Avian leukosis/sarcoma group viruses (ALSV), reticuloendotheliosis viruses (REV), and lymphoproliferative disease virus of turkeys (LPDV) (King *et al.*, 2012d).

ALSV belongs to the genus *Alpharetrovirus*, which is able to induce erythroid, lymphoid, and myeloid leukoses and other kind of tumors in chickens and other species of birds. Lymphoid neoplasms (B cell origin) are usually induced by ALVs subgroups A and B. The erythroid leukosis originates from bone marrow cells and is induced by subgroup J ALVs. Myeloid leukosis derives from myeloid (granulocytic) cells of the bone marrow and produce myeloblastosis and myeolocytomatosis (Venugopal *et al.*, 2000). Additionally, ALSVs and specially ALV-J are associated with the induction of other tumors, such as fibrosarcomas, chondroma, hystiocytic sarcoma, endothelioma, hemangioma, nephroblastoma, and hepatocarcinoma. Furthermore, these viruses are able to induce osteopetrosis (Nair and Fadly, 2013).

REV includes several viruses isolated from game birds (order *Galliformes*) and waterfowl (order Anseriformes). REVs induce an acute multisystemic and neoplastic disease in chickens and turkeys, or in chronic cases, formation of B-cell or T-cell lymphomas (Nair *et al.*, 2013).

Bacterial Diseases

Avian Cholera

Fowl cholera is caused by *Pasteurella multocida*, which is a Gram-negative, nonmotile, non-spore-forming, rod-shaped bacterium. The species *P. multocida* includes the subspecies multocida, septica, and gallicida. Additionally, *P. multocida* is divided into 16 somatic serovars (1–16) and five capsular serovars (A, B, C, D, and E). All capsular and somatic serovars (with exception of 8 and 13) have been isolated from birds. However, subspecies multocida serovar A is the most frequently isolated one in cases of fowl cholera. All types of birds are susceptible to the infection, but turkeys, partridges, and pheasants are highly susceptible.

Pasteurella multocida first colonizes the upper respiratory tract and lung and later disseminates, causing two clinical presentations. The peracute/acute form is related to septicemia, inducing petechial to ecchymotic hemorrhages in the heart, the mucous membranes of the gizzard, and in the abdominal fat. In chronic cases, lesions involve the respiratory tract (fibrinonecrotic pneumonia and fibrinopurulent pleuritis), the conjunctiva, infraorbital sinuses, and the reproductive tract. *Pasteurella multocida* is also related to fibrinonecrotic dermatitis affecting the dorsum, abdomen, and breast (Glisson *et al.*, 2013).

Pasteurella multocida infections are notifiable due to their zoonotic potential (Wilson and Ho, 2013).

Mycoplasmosis

Mycoplasmas are assigned to the class mollicutes, which comprises the smallest known prokaryotes able to replicate in cell-free medium. There are 23 recognized avian mycoplasma species, but only four species are important in poultry.

Mycoplasma gallisepticum

Mycoplasma gallisepticum infects chickens, turkeys, pheasants, partridges, duck, geese, guinea fowl, quail, peafowl, racing

pigeons, and other species of free-living birds. *Mycoplasma gallisepticum* causes catarrhal rhinitis, tracheitis, pneumonia, edema of the air sac walls, and sinusitis (Gharaibeh, 2011).

Mycoplasma synoviae

Mycoplasma synoviae strains vary in their virulence and tropism. *Mycoplasma synoviae* affects primarily chickens and turkeys, and less frequently guinea fowl, ducks, geese, pigeons, quails, pheasants, Red-legged Partridges, and house sparrows. *Mycoplasma synoviae* may cause respiratory lesions or suppurative and caseous arthritis of the foot and hock joints (Osorio *et al.*, 2007).

Mycoplasma meleagridis

Mycoplasma meleagridis is a specific pathogen of turkeys that causes airsacculitis, osteodystrophy, and low hatchability in mature birds (Chin, 2013).

Mycoplasma iowae

Mycoplasma iowae contains six serovars, which vary in their virulence. *Mycoplasma iowae* causes embryo mortality in turkey, poor-quality poults, and chondrodystrophy (Bradbury and Raviv, 2013).

Chlamydiosis – Chlamydophilosis

Avian chlamydophilosis is produced by bacteria belonging to the family Chlamydiacea, which is divided in two genera: *Chlamydia* and *Chlamydophyla*. The species that affect birds belong to the genus *Chlamydophyla* and include the following: *Chlamydophyla pecorum* and *Chlamydophyla psittaci*. These are Gram-negative, coccoid bacteria that depend on the intracellular environment for their multiplication. (Vanrompay, 2013).

Chlamydophyla psittaci infects parrots and other psittacine birds as well as domestic poultry and free-living birds. Infected birds can transmit the infection to mammals (Beeckman and Vanrompay, 2009).

Severity of the disease varies according to the strain of *C. psittacine*. High-virulent strains are related to acute epidemics and high mortality, whereas low-virulent strains spread slowly and cause slightest lesions. Birds affected acutely show fibrinous peritonitis, pericarditis, myocarditis, pneumonia, and enlargement of the liver and spleen, which also show multifocal necrosis. Chronically infected birds show hepatomegaly and splenomegaly, which may lead to rupture of these organs (Vanrompay, 2013).

Ornothobacterium and *Riemerella*

Ornothobacterium and *Riemerella* genera belong to the family Flavobacteriaceae.

Ornithobacterium rhinotracheale

Ornithobacterium rhinotracheale is a slow-growing, Gram-negative, pleomorphic or rod-shaped bacterium that has been isolated from chicken, Chukar Partridge, duck, goose, guinea fowl, gull, pheasant, ostrich, partridge, pigeon, quail, rook, and turkey. Infection in broiler chickens induces purulent airsacculitis, pleuritis, and pneumonia (Chin *et al.*, 2013). Young birds can also have purulent inflammation of the brain and osteomyelitis of the skull bones (Moreno *et al.*, 2009).

Riemerella anatipestifer

Riemerella anatipestifer is a Gram-negative, nonsporulated bacterium that causes disease not only in young ducks but also in galliform birds, such as turkeys, pheasants, and partridges. Lesions produced by *R. anatipestifer* include fibrinous airsacculitis, polyserositis, sinusitis, pneumonia, meningitis, mucopurulent, or caseous salpingitis (Ruiz and Sandhu, 2013).

Enterobacteriaceae

The family Enterobacteriaceae consists of rod-shaped, Gram-negative aerobic or facultative anaerobic bacterium. This family includes bacteria within the genera *Salmonella*, *Escherichia*, *Shigella*, *Citrobacter*, *Klebsiella*, *Proteus*, and *Yersenia* (Lister *et al.*, 2008).

Salmonella

This genus consists of two species: *Salmonella enterica* and *Salmonella bongori*. The former contains 6 subspecies that are also classified in serovars according to the antigenic specificity. In the veterinary field, the most important serovars are: *Salmonella* pullorum (pullorum disease), *Salmonella* gallinarum (fowl typhoid), *S. enterica* subsp. *arizonae* (Arizonosis), and other salmonella infection-causing serovars (Salmonellosis, paratyphoid infection) (Lister *et al.*, 2008).

- Pullorum disease: Almost all species of birds can get infected with *S.* pullorum, but only chickens, turkeys, guinea fowl, quail, and pheasant show clinical disease. Clinical signs are usually observed in birds less than 3 weeks of age, which are found dead in shell or die quickly after hatching, due to peritonitis and septicemia (Shivaprasad, 2013b).
- Fowl typhoid (*Salmonella* gallinarum infection): *S.* gallinarum causes disease mainly in adult or growing chickens and turkeys but also affects ducks, pheasants, guinea fowl, peafowl, grouse, and quail. Acute cases of infection are related to septicemia. In subacute outbreaks, there are dead-in-shell embryos, or dead chicks on the hatching trays. Chronically affected birds show anemia and focal necrosis in the liver (**Figure 2**), heart, intestines, and pancreas (Lister *et al.*, 2008).
- Salmonellosis, paratyphoid infection: Within this group are included *Salmonella* serovars associated with foodborne human disease. This group includes *Salmonella* enteritidis and *Salmonella* typhimurium. Members of this group are found in a wide range of species (birds, mammals, reptiles, fish, and insects). Paratyphoid *S. enterica* produces typhlitis in young birds with dissemination toward the spleen, lungs, liver, spleen, and kidneys (Gast, 2013).
- Arizonosis (*S. enterica* subsp. *arizonae*): Arizonae infection affects avian, mammal, and reptilian species. Avian arizonosis is recognized mainly in turkeys but also is found in chickens and ducks. Clinical signs are similar to the observed in cases of salmonellosis, but additionally the

Figure 2 Liver from a bird naturally infected with *Pasteurella*, showing hepatomegaly and multifocal-coalescing pale foci of necrosis and hemorrhages. Photos provided by Alejandro Alfaro, Universidad Nacional de Costa Rica.

arizonosis is characterized by the induction retinitis and encephalitis (Shivaprasad, 2013a).

Collibacillosis

Escherichia coli (*E. coli*)species are Gram-negative bacteria, flagellated rods that are normal inhabitants of the digestive tract in birds and mammals. Collibacillosis entitle all disease conditions that are caused by the pathogenic serovars of *E. coli*, including Colisepticaemia, egg peritonitis, and yolk sac infection or omphalitis, coligranuloma, swollen head syndrome, and others syndromes (Lister *et al.*, 2008).

- Colisepticemia is observed in chickens, turkeys, ducks, and pheasants. Birds affected show pericarditis, perihepatitis, airsacculitis, and peritonitis.
- Egg peritonitis is observed in chickens, turkeys, ducks, and geese. Gross findings include peritonitis, salpingitis, and impaction of the oviduct.
- Yolk sac infection occurs by contamination of the unhealed navel or by contact of the hatching egg with the contaminated shell. Chickens affected show septicemia and yolk sack inflammation.
- Coligranuloma consists of several hard, yellow, nodular granulomas that are found in the mesenteries and wall of the intestines, especially in the cecum.
- Swollen head syndrome (SHS) is observed in chickens, turkeys, and guinea fowl and consists of an acute to subacute cellulitis affecting the periorbital tissues (Nolan *et al.*, 2013).

Clostridia

Clostridia are large Gram-positive, rod-shaped, toxin-producing bacteria that generate endospores to survive. Clostridia are ubiquitous worldwide and are found in the soil, dust, animals, and insect larvae. They are considered normal inhabitants of the intestinal tract (Kaldhusdal *et al.*, 2008).

Clostridium perfringes *(necrotic enteritis-NE and hepatic disease)*

Clostridium perfringes causes two types of diseases: necrotic enteritis (NE) and colangiohepatitis. NE is caused by *C. perfringes* toxin types A and C and is observed mainly in chickens and turkeys but also found in ostriches, wild geese, wild crows, domestic geese, and ducks. NE occurs when predisposing factors (such as infection with *Eimeria*) induce overgrowth of *C. perfringes*, which through its toxins destroys the cell membranes, causing pseudomembranous enteritis (**Figure 2**) and endotoxemia. Cholangiohepatitis is related to *C. perfringes* toxin type A producers that arrive to the liver via the portal blood or bile, causing cholangitis, and occasionally focal necrosis, granulomas, and rarely massive liver necrosis (Opengart and Glenn Songer, 2013).

Clostridium colinum *(ulcerative enteritis)*

Clostridium colinum affects mainly quails but also infects chickens, turkeys, pheasants, partridges, grouse, pigeons, robins, and lories. *Clostridium colinum* induces ulcerative, pseudomembranous enteritis that affects the small intestine, ceca, and upper large intestine. The ulcers may become perforated, generating peritonitis (Songer and Uzal, 2013).

Clostridium botulinum *(botulism and limberneck)*

Botulism is a paralytic disease caused by toxins produced by *C. botulinum*. There are seven toxins (A–G); Toxin type C is the most important and common one. Presence of type C botulism has been described in chickens, turkeys, ducks, gulls, pheasants, and ostriches (Skarin *et al.*, 2013).

Gangrenous dermatitis (malignant edema and cellulitis)

Gangrenous dermatitis is observed in chickens and turkeys. The disease is caused by *Clostridium septicum* and *C. perfringes* type A, and occasionally *Staphylococci aureus* (Opengart, 2013).

Campylobacter

The genus *Campylobacter* consists of curved-rod, Gram-negative, flagellate bacteria, which grow at high temperatures (42–43 °C). These organisms are found normally in the intestinal tract of a wide variety of animals, including birds (Whiley *et al.*, 2013). Their significance lies in the ability to cause disease in humans, producing catarrhal diarrhea and self-limiting fever or in severe cases nervous system manifestations. In birds there are three main species: *Campylobacter jejuni*, *Campylobacter coli*, and *Campylobacter lari*. *Campylobacter jejuni* is usually found in poultry but can also be isolated from game birds, pigeons, and several wild bird species. Besides, poultry farm workers act as carriers and can spread the infection between broiler houses and farms. Therefore, all biosecurity

measures have to be directed to reduce the horizontal transmission of the bacteria (Hermans, 2012).

Tuberculosis

Avian tuberculosis occurs in companion, captive exotic, and wild and domestic birds throughout the world. *Mycobacterium avium* consists of a complex group of mycobacterial organism, which is divided into four subtypes: *M. avium* subsp. *avium*, *M. avium* subsp. *hominissuis*, *M. avium* subsp. *silvaticum*, which are pathogens of birds, and *M. avium* subsp. *paratuberculosis*, which is a pathogen of mammals (Dhama, 2011).

Mycobacterium avium infects all species of birds, among which the most susceptible ones are the domestic species (such as chickens, ducks, and geese), game birds (pheasants), and birds kept in zoos (Moreno *et al.*, 2011). In poultry, *M. avium* subsp. *avium* serotypes (1, 2, and 3) are the most virulent ones and are most frequently found. *Mycobacterium avium* subsp. *avium* produce tubercular granulomas that may be found in the intestines, liver, spleen, bone marrow, and other tissues (Fulton and Sanchez, 2013).

Other Bacterial Diseases

Yersinia pseudotuberculosis *(Yersiniosis)*

Yersinia pseudotuberculosis (Yersiniosis) is a Gram-negative coccobacillus that causes severe enteritis, splenomegaly, hepatomegaly, and lung lesions in young turkeys. In chronic cases it is possible to observe caseous tubercle-like lesions in the liver, spleen, and lungs (Lister *et al.*, 2008).

Avibacterium paragallinarum

Avibacterium paragallinarum is a Gram-negative, non-spore-forming, capsulated rod-shaped bacterium that causes coryza in chickens. The lesions consist of catarrhal and fibrinopurulent inflammation of the nasal passages, infraorbital sinuses, and conjunctivae in old birds (Blackall, 1999).

Gallibacterium anatis

Gallibacterium anatis is a Gram-negative, rod-shaped, or pleomorphic bacterium that is a normal inhabitant of the upper respiratory tract and the lower genital tract. *Gallibacterium anatis* produces purulent salpingitis and oophoritis in chickens, turkeys, geese, ducks, pheasants, partridges, cage bird, and wild birds. In chronic cases purulent peritonitis may be found (Paudel *et al.*, 2013).

Bordetella avium

Bordetella avium is a Gram-negative, rod-shaped bacterium. *Bordetella avium* causes turkey coryza, which is an acute respiratory tract disease in young turkeys. Lesions consist of mucopurulent pneumonia and respiratory stress syndrome. *Bordetella avium* also infects young Muscovy ducks, quail chicks, and cockatiels (*Nymphicus hollandicus*) (Jackwood and Saif, 2013).

Erysipelothrix rhusiopathiae

Erysipelothrix rhusiopathiae is a Gram-positive, rod-shaped bacterium. There are 26 serovars of *E. rhusopathiae*, but only the serovars 1, 2, and 5 produce outbreaks. *Erysipelothrix rhusiopathiae* is found in pigs, rodents, fish, and birds, and rarely in sheep. In birds, *E. rhusopathiae* infects turkeys, chickens, ducks, geese, emus, pigeons, and game birds. Birds acutely affected show lesions indicative of septicemia, such as petechial hemorrhages in the myocardium, epicardium, gizzard serosa, mesentery, liver, and pleura. In chronic cases, there is vegetative endocarditis and fibrinopurulent arthritis (Bricker and Saif, 2013). *Erysipelothrix rhusiopathiae* in humans may cause erysipeloid (localized infection of the fingers and hands), generalized cutaneous infections and septicemias (Wang *et al.*, 2010).

Staphylococci, Streptococci, and enterococci

- Staphylococci consist of Gram-positive cocci belonging to the family Micrococcaceae and genus *Staphylococcus*. The genus includes 40 species, of which *Staphylococcus aureus* is the most important and common one in poultry. *Staphylococcus aureus* may cause septicemia, fibrinous arthritis and tenosinovitis, chondronecrosis, and osteomyelitis (also called femoral head necrosis) in chickens, turkeys, ducks, and geese (Andreasen, 2013).
- Streptococci and Enterococci of importance in poultry include *Streptococcus gallinaceus*, *S. gallolyticus*, *S. equi* subsp. *zooepidemicus*, *Enterococcus hirae*, *E. durans*, and *E. faecalis*. Lesions associated with infections by Streptococci and Enterococci consist of septicemia (common in chickens, ducks, and pigeons), caseous cellulitis (caused by *S. dysgalactia* in chickens and turkeys), encephalomalacia (associated with *E. durans* and *E. hirae*), vegetative endocarditis (caused by *E. hirae* in young birds and *E. faecalis* in older birds), and amyloid arthropathy (observed in chickens infected with *E. faecalis*) (Thayer and Waltman, 2013).

Fungal Diseases

Fungi are eukaryotes that nourish through absorption and can exist as single-celled or multicelled organisms. They are opportunistic pathogens of all species of birds and cause disease by tissue invasion or by means of the production of toxins (Dykstra *et al.*, 2013)

Aspergillosis (Brooder Pneumonia)

Species of *Aspergillus* associated with disease include the following: *Aspergillus fumigatus*, *A. flavus*, *A. niger*, *A. glaucus*, and *A. terreus*. *Aspergillus* species are soil saprophytes. Birds are infected by inhalation of conidia, which may germinate and produce granulomatous lesions in the respiratory tract and air sacs epithelium (**Figure 3**). Besides, conidia may invade the blood vessels and spread to other tissues, such as the brain, pericardium, bone marrow, kidneys, and other soft tissues. Keratoconjunctivitis or panophthalmitis can also be observed (Dykstra *et al.*, 2013).

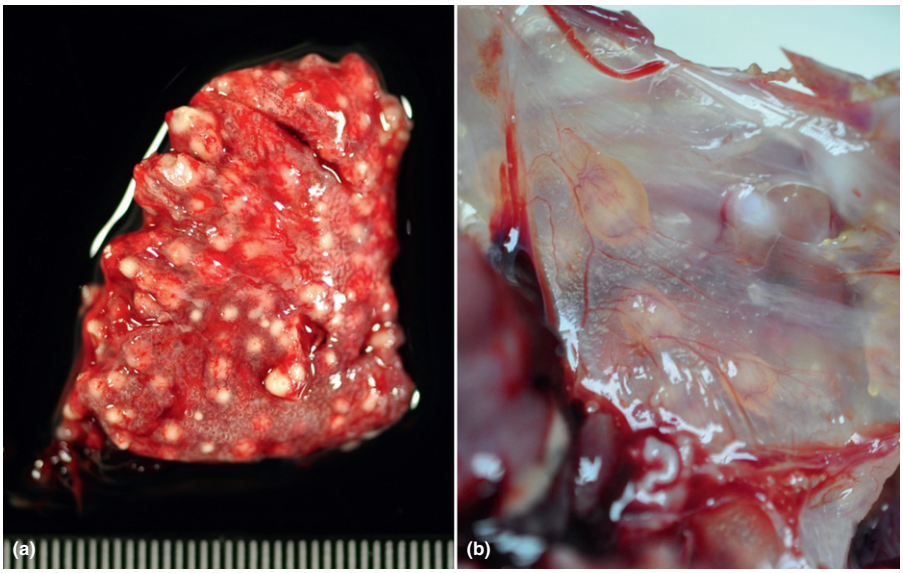

Figure 3 (a) Lung and air sacs. (b) Lung from naturally infected chickens showing numerous caseous nodules characteristic of respiratory asperigllosis. Photo (a) was provided by Natàlia Majó i Masferrer, SDPV (Servicio de Diagnóstico de Patología Veterinaria)-CReSA (Centre de Reserca en Sanitat Animal, Barcelona) and Photo (b) was provided by Alejandro Alfaro, Universidad Nacional de Costa Rica.

Other Fungal Diseases

Ochroconosis

Ochroconiosis (formely Dactylariosis) is a rare neurological disease of chickens and turkeys poults that is caused by *Ochroconis gallopava*.

Candidiasis (crop mycosis, thrush)

Candida albicans yeast produces pseudomembranes and diphtheric membranes in the oral cavity, esophagus, and crop of immunosuppressed birds. In rare cases, it is associated with neurological, renal and intestinal disease.

Favus (white comb, ringworn)

Favus is a skin disease caused by *Microsporum gallinae* (formely *Trichophyton gallinae*) that affects mainly the unfeathered skin (comb, wattle, and shanks) and occasionally the feathered skin (Dykstra *et al.*, 2013).

Mycotoxicosis

Mycotoxins are chemical by-products produced by fungi that are toxic to animals (mycotoxins) and/or to bacteria (antibiotics) or both. They are produced when the fungi invade the grain or feed, and there are adequate temperate, moisture, and grain substrate to growth. The most frequent mycotoxicosis in birds include the following: aflatoxicosis, ochratoxicosis, and tricothecene mycotoxicosis (Hoerr, 2013).

Aflatoxicosis

Aflatoxins are toxins produce by *Aspergillus flavus*, *A. parasiticus*, and *Penicillium puberulum*, which are found in corn, millet, sorghum, and other feed grains. Fungi growth is favored by warm and high humidity conditions. Aflatoxins consist of several mycotoxins (B1, B2, G1, and G2), of which the most toxic and usual one is Aflatoxin B1. This aflatoxin is biotransformed in a highly reactive metabolite that binds to the DNA and RNA, impairing the protein synthesis and immunity. Aflatoxins cause liver enlargement due to lipidosis and hyperplasia of the biliary ducts. Blood clotting factor synthesis and capillary stability are altered; as a result birds may show petechial hemorrhages or bruises.

Ochratoxicosis

Ochratoxin is a dihydroisocoumarin derivative produced mainly by *Aspergillus ochracues* and *Penicillium veridicatum*. Ochratoxin A is the most common and toxic one. Ochratoxin A inhibits proteins synthesis, producing anemia, immunosuppression, and decrease in egg production and hatchability. It also causes acute necrosis in the kidneys and visceral gout.

Trichothecene mycotoxicosis

Trichothecene mycotoxins are found in wheat, corn, and other grains contaminated with species of *Fusarium*, *Stachybotrys*, and other genera of fungi that prefer cold and moist conditions for growth. Trichothecene mycotoxins cause lesions through two mechanisms: direct epithelial necrosis or radiomimetic effects. For example, T-2 toxin and DAS cause necrosis of the epithelial cells of the commissures of the mouth, hard palate, the dorsal surface of the tongue, and rostral part of the oropharynx. Mycotoxins inducing radiomimetic effects inhibit the synthesis of proteins and reduce cellular life span and therefore affect the hematopoiesis, lymphopoiesis, immune response, and the replication of feather follicle epithelium and enterocytes (Hoerr, 2013).

Other Micotoxicosis

Fusarium *fungi – Moliniformin*

Moliniformin is produced by *Fusarium verticillioides* (formerly *F. moliniforme*) and other *Fusarium* spp. This toxin causes reduced performance and diarrhea. Experimentally, it induces acute myocardial necrosis, nephrosis, and death.

Fumonisins

Fumonisins are also produced by *Fusarium verticillioides* and cause catarrhal enteritis, liver necrosis, villous atrophy in the intestines, lymphoid depletion, and rickets.

Fusarochromanone (TDP-1)

TDP-1 is produced by *Fusarium* spp. and is related to leg deformities and tibial dyschondroplasia in chickens.

Oosporein

Oosporein is produced by *Chaetomium* spp and induces acute proximal tubular nephrosis and gout.

Ergotism

Ergotism is an acute disease caused by alkaloid toxins produced by *Claviseps* species, particularly *Claviseps purpurea*. Ergotism causes vascular, neurological, and endocrine disorders. Birds affected may show reduced growth and egg production, diarrhea, and necrosis as well as ulcers affecting the unfeathered skin of the comb, wattles, beak, and feet (Hoerr, 2013).

Parasitic Diseases

Coccidiosis

Coccidiosis is one of the most important diseases of poultry caused by parasites worldwide. Coccidia are intracellular protozoa parasites that belong to the phylum Apicomplexa. In poultry, most coccidia are classified within the genus *Eimeria*, which are highly host specific.

Chicken coccidiosis may be attributed to seven species of *Eimeria*, which are: *E. brunetti*, *E. necatrix*, *E. tenella*, *E. acervulina*, *E. maxima*, *E. mitis*, and *E. precox*. *Eimeria tenella* and *E. necatrix* are the most pathogenic species and are associated with necrohemorrhagic typhlitis. *Eimeria. acervulina* and *E. maxima* are the most prevalent ones and cause lesions in the small intestine. Turkeys are infected by coccidian of the following species: *E. adenoeides*, *E. meleagridis*, *E. gallopavonis*, and *E. meleagrimitis*. Intestinal coccidiosis can also be seen in geese, ducks, game birds, and pigeons. Infected birds may show diarrhea as a consequence of catarrhal to necrohemorrhagic enteritis. In general, infection with one species of *Eimeria* does not ensure protection against other species, neither does maternal antibodies; however, repetitive exposure to low numbers of oocyst does give protection (McDougald and Fitz-Coy, 2013).

Cryptosporidiosis

Cryptosporidia are apicomplexan protozoa parasites that affect mammals and birds. *Cryptosporidium baileyi* causes respiratory disease and *C. meleagridis* produces enteric infections. Cryptosporidia parasitize the margin of the epithelial cells, where it is enclosed by the cell membrane. Infection and disease have been reported in chickens, turkeys, ducks, pheasant, quail, peafowl, and other birds. In the respiratory form, cryptosporidia causes sinusitis, conjunctivitis, pneumonia, and airsacculitis. The enteric infection is associated with poor performance (McDougald, 2013a).

Histomoniasis (Blackhead)

Histomoniasis is an enterohepatitis caused by the protozoan *Histomonas meleagridis*. It is observed mainly in turkey poults but game birds, chickens, and guinea fowl may also be affected. Birds get infected after ingestion of eggs of the cecal nematode *Heterakis gallinarum* female parasites (intermediate host), which are transported by earthworms or remain alive in the soil (Armstrong and McDougald, 2011). *Histomonas meleagridis* causes ulcerative or hemorrhagic typhlitis and multifocal zones of necrosis in the liver. Liver lesions, which appear 10–12 days postinfection, are pathognomonic (Hess and McDougald, 2013).

Other Protozoa Parasites

Spironucleosis-Hexamitiasis

Spironucleus meleagridis causes slight catarrhal enteritis in turkey poults and young game birds.

Trichomonas gallinae

This pathogen produces necrotic and caseous lesions in the mouth, crop, and esophagus of pigeons and squabs and rarely in turkeys and chickens. Occasionally, there are systemic lesions involving the liver.

Leucocytozoonosis

Leucocytozoon spp. infects blood and tissue cells and is described in ducks and geese (*L. simondi*), turkeys (*L. smithi*), and chickens (*L. caulleryi, L sabrasezi*, and *L. choutedeni*). Within its life cycle, schizogony is found in the liver, lungs, heart, brain, and spleen, whereas gamonts are contained within blood cells. Infected birds show weakness, anemia, and mortality (Hess and McDougald, 2013).

Nematode Parasites

In birds there are a great number of nematode parasites; however, their prevalence in poultry birds is low, because half of them require an intermediate host. Therefore, they are more frequent in free-range, backyard, and wild birds. Most nematodes affect the gastrointestinal tract, such as *Capillaria*, which causes enteritis (*C. obsignata, C. annulata, etc.*), *Heterakis* (important in the life cycle of *Histomonas*), and Ascaridia (*Ascaridia galli* that affects performance in heavy infestations). In addition, there are nematodes that have affinity for the respiratory tract, such as *Syngamus trachea* and *Cyathostoma bronchialis*. The first one affects wild and domestic birds and causes blockage of the trachea, whereas *C. bronchialis* is a parasite of geese (McDougald, 2013b).

Cestodes and Trematodes

Cestodes and trematodes require intermediate hosts in their life cycles. Cestodes employ arthropods, whereas trematodes need molluscan. Therefore, their importance as pathogens of modern poultry production systems is insignificant. However, they are still relevant in free-range rearing, game, and wild birds, causing digestive and reproductive tract lesions (McDougald, 2013b).

Ectoparasites

Ectopasites of birds include species of lice, such as *Menacanthus stramineus*, *Cuclotogaster heterographa*, and *Menopon gallinae*, which feed on feathers and skin scales causing irritation.

Moreover, birds may be seriously infested by mites that cause anemia due to their blood-sucking habits. The most important mites in poultry are *Dermanyssus gallinae* (red mite) and *Ornothonyssus sylvarum*. *Dermanyssus gallinae* infects chickens and other species of birds.

Fleas may also cause irritation and blood loss. Fleas infest the host and persist in the environment; some of them, such as *Echidnophaga gallinacea*, can be attached to the host for months. Finally, ticks may cause poor food conversion, depressed egg output, and anemia (Hinkle and Corrigan, 2013).

Nutritional Disorders

Nutritional imbalances may arise from deficiency in the diet, destruction or inactivation during feed processing and manufacture, antagonism between nutrients, or impaired absorption and metabolism. Each of the 36 essential nutrients of poultry has specific functions that account for the distinctive diseases associated with its deficiency (summarized below). However, in the field, only rarely these changes are related to deficiency of one specific element (mineral, vitamins, etc.), making the clinical diagnosis a difficult task (Klasing, 2013).

Vitamin A (Retinol, Retinoic Acid, and Retinyl Ester)

Vitamin A is necessary to maintain the epithelial function and structure and also for a normal egg production. Consequently, its deficiency is related to epithelial and mucous metaplasia of the respiratory, intestinal, and urinary tracts. Pathognomonic hyperkeratotic lesions are observed in the cornea and the skin of the mouth and esophagus. The excess of this vitamin induces deficiency of vitamin E and D_3 (Klasing, 2013).

Vitamin D (Cholecalciferol-Vitamin D_3)

Vitamin D acts as a hormone to regulate calcium and phosphorus metabolism. Deficiency of vitamin D causes growth retardation, rachitic deformities, osteomalacia, osteoporosis, tibial dyschondroplasia, and egg abnormalities in layers. Excess of vitamin D is toxic, as a consequence of the deposition of calcium in several soft tissues (Klasing, 2013).

Vitamin E (α-Tocopherol)

Vitamin E is an antioxidant that has a major role in the protection of cellular membranes. Clinical conditions associated with its deficiency include the following: embryonic mortality in breeders, encephalomalacia, exudative diathesis, and nutritional muscular dystrophy in young birds (**Figure 4**). The security index of vitamin E is very high and therefore toxicity is improbable (Klasing, 2013).

Vitamin K (Vitamin K_3-Menadione)

Vitamin K participates in the formation of prothrombin and so in blood coagulation. It also contributes in calcium metabolism. Deficiency causes delayed blood clotting (Klasing, 2013).

Vitamin B_1 (Thiamin)

Vitamin B_1 participates in the metabolism of carbohydrates. Deficiency of this vitamin is rarely seen in the field, unless feed that contains thiaminase (such as fishmeal) or treatments with the anticoccidial amprolium have been used. Deficiency affects the overall performance (Klasing, 2013).

Vitamin B_2 (Riboflavin)

Riboflavin acts as coenzymes in several enzyme systems; many of them are related with oxidation–reduction reactions in the process of cellular respiration. Deficiency causes reduced egg production. Hatched chickens may be dwarfed, show depigmentation, and 'curled toe paralysis' due to the presence of degenerative changes in nerve trunks (Cai *et al.*, 2009).

Vitamin B_6 (Pyridoxine)

Vitamin B_6 participates in the metabolism of amino acids. As a consequence, there is no specific list of signs related to its

Figure 4 Pectoral muscles of a chicken affected with vitamin E and selenium deficiency, showing severe locally extensive areas of degeneration and necrosis, which is noted by the presence of light colored streaks of affected muscle. Photos provided by Natàlia Majó i Masferrer, SDPV (Servicio de Diagnóstico de Patología Veterinaria)-CReSA (Centre de Reserca en Sanitat Animal, Barcelona).

deficiency. Birds showing deficiency may have anemia, demyelinization, weakness, paresis, and chondrodysplasia (Klasing, 2013).

Niacin (Nicotinic Acid and Nicotinamide – Vitamin B_3)

Niacin is part of the coenzymes involved in metabolism of proteins, carbohydrates, and fats. Deficiency in birds causes poor growth, feather disorders, inflammation of the mucous membranes of the alimentary tract, nervous degeneration, and chondrodystrophy in young birds (Klasing, 2013).

Pantothenic Acid (Vitamin B_5)

Pantothenic acid is required to synthesize coenzyme A (CoA), which has a role in energy and fatty acid metabolism, citric acid cycle, neural function, antibody formation, and endocrine function (steroid hormones). Deficiency causes dermatitis, drop in egg production, embryo death, and stunted and weak chickens (Klasing, 2013).

Biotin (Vitamin H)

Biotin is necessary for the production of fatty acids, carbohydrates, and proteins; therefore, it is essential for growth, epidermal and tissue maintenance, bone development, and reproduction. Deficiency induces reduced growth and hatchability, deformed embryos, dermatitis (footpad, toes, and periocular), and beak deformities. Occasionally, there is chondrodystrophy and fatty liver and kidney syndrome (FLKS) in young broilers and layer pullets (Klasing, 2013).

Folic Acid (Folacin)

This vitamin acts as a coenzyme in the synthesis of specific amino acids (e.g., purines, choline, threonine, and histidine). Consequently, it is indispensable for nucleic acid synthesis and cell mitosis. Folic acid deficiency causes macrocytic megaloblastic anemia, defective feather development and pigmentation, chondrodystrophy, and cervical paralysis in young birds. Breeding birds show reduced hatchability and presence of embryo deformities (Klasing, 2013).

Vitamin B_{12}

Vitamin B_{12} is involved in metabolism of proteins, carbohydrates, and fats. Deficiency produces embryonic death and lowered hatchability. Chick embryos affected show malposition, myopathy, and chondrodystrophy (Klasing, 2013).

Choline

Choline is part of various phospholipids (e.g., lecitin) and is necessary to maintain the cell structure (especially of cartilage) and fat metabolism. Choline also participates in nerve transmission (forms the acetylcholine) and protein synthesis as methyl group donor. Deficiency causes reduced growth rate and hatchability, chondrodystrophy, and fatty liver (Klasing, 2013).

Calcium and Phosphorus

Calcium and phosphorus are part of body fluid electrolytes. Calcium participates in nerve cell excitation, neuromuscular transmission, muscular contraction, and blood clotting. Phosphate is necessary to maintain the acid–base balance and protein and carbohydrate metabolism. Calcium and phosphorus imbalance may cause rickets in growing birds and osteomalacia or osteoporosis in mature animals. Affected laying hens produce eggs with thin or soft shell and may show paralysis, fractures, and have skeletal deformities. However, excess of calcium causes nephropathy with renal fibrosis, atrophy, and visceral gout. An excess of phosphorus decreases the quality of the eggshell and increases bone fragility in layer birds (Klasing, 2013).

Sodium Chloride

Sodium chloride is a component of the intra- and extracellular fluids; as a result, it is important to maintain the acid–base and water balance as well as for transfer of metabolites across membranes and nerve impulse transmission. Birds fed with low levels of sodium show severe drop in egg production, pecking behavior, and cannibalism. An excess of sodium produces diarrhea, excessive thirst, progressive muscular weakness, convulsions, and death. Young birds show severe kidney damage with presence of visceral gout (Klasing, 2013).

Manganese

Manganese is necessary, along with magnesium, in the activation of several enzymatic systems and formation of DNA complex. Deficiency in young birds produces growth retardation and bone deformities (e.g., chondrodystrophy). Laying or breeding birds may show decreased egg production and hatchability, in addition to embryo mortality, ataxia, and tetanic spasms in newly hatched chicks (Klasing, 2013).

Zinc

Zinc participates in almost every metabolic function in the organism; therefore, its deficiency has a great impact on the development of the skeleton and in the reproductive system. Growing birds exhibit poor feathering and scaly skin, in addition to chondrodystrophy. Laying birds show decreased egg production and hatchability. Embryo mortality with presence of deformities is observed around mid-incubation (Klasing, 2013).

Selenium

Selenium forms part of the cell enzyme glutathione peroxidase and acts in accordance with vitamin E as antioxidants. Deficiency causes muscular dystrophy (**Figure 4**), exudative diathesis, and encephalomalacia (Klasing, 2013).

Toxicants

Toxicity is almost always determined by the dose, because it is possible to find cases of toxicoses related to the use of apparently innocuous substances, such as feed constituents or therapeutic agents. Many of these toxicoses cause unspecific clinical signs that could be confused with infectious and metabolic diseases. Diagnosis depends on the compilation of a

Table 1 List of diagnostic methods and sample selection for the most important – notifiable viral diseases of poultry

Methods of diagnosis for viral-origin poultry and avian diseases

Infectious agent	*Samples of choice*	*Serological techniques – Immune status*	*Etiological diagnosis – Antigen detection*
Avian influenza virus	● Live birds: oropharyngeal and cloacal swabs and serum ● Dead birds: feces, trachea, lung, air sacs, intestines, spleen, kidney, brain, liver, and heart	● AGID ● HA test and HI test ● ELISA	● Virus isolation in SPF embryonated chicken eggs ● AC-ELISA ● Immunofluorescence and immunohistochemistry ● RT-PCR and rRT-PCR techniques
Newcastle virus	● Live birds: oropharyngeal and cloacal swabs and serum ● Dead birds: oronasal swabs, lung, kidneys, intestines, cecal tonsils, spleen, brain, liver, and heart	● HA test and HI test ● ELISA	● Virus isolation in SPF embryonated fowl eggs ● RT-PCR and rRT-PCR techniques
Infectious bronchitis virus	● Live birds: oropharyngeal swabs and serum ● Dead birds: oropharyngeal swabs, trachea, lung, kidneys, and oviduct	● HA test and HI test ● AGID ● VN ● ELISA	● Virus isolation SPF embryonated chicken eggs ● TOC ● Immunofluorescence and immunohistochemistry ● RT-PCR ● RT-PCR-RFLP
Infectious Laryngotracheitis virus	● Live birds: tracheal, oropharyngeal or conjunctival swabs, and serum ● Dead birds: tracheal samples and mucosal scrapings	● AGID ● ELISA	● Virus isolation in SPF embryonated chicken eggs or cell cultures. ● Immunofluorescence ● Histopathology (Cowdry type A inclusions) ● PCR and PCR-RFLP
Poxvirus	● Cutaneous tissue samples or smears of the diphtheritic lesions and serum	● Passive HA test ● AGID ● VN ● ELISA	● Smears stained with Giménez method. ● Virus isolation in SPF embryonated chicken eggs or cell cultures. ● Histopathology (intracytoplasmatic inclusions – Bollinger bodies), Immunofluorescence and immunoperoxidase ● PCR-RFLP ● Immunoblotting or Western Blotting
Infectious bursal disease	● Live birds: serum ● Dead birds: bursa of Fabricius tissue samples	● AGID ● VN ● ELISA	● Virus isolation in specific antibody-negative chicken embryos or cell cultures Immunofluorescence ● AC-ELISA ● RT-PCR and RT-PCR-RFLP
Marek's disease	● Blood samples (Buffy coat cells), lymphoma and spleen tissue samples, and feather	● AGID ● ELISA	● Virus isolation in cell cultures. ● PCR ● Real time quantitative-PCR

Abbreviations: AGID, agar gel immunodiffusion; HA, hemagglutination; HI, hemagglutination inhibition; ELISA, enzyme-linked immunosorbent assay; SPF, specific pathogen free; AC, antigen capture; RT-PCR, reverse transcription polymerase chain reaction; rRT-PCR, real time RT-PCR technique; VN, virus neutralization; TOC, tracheal organ culture; and RT-PCR-RFLP, RT-PCR-restriction fragment length polymorphism.

Paris, France: World Organisation for Animal Health, Section 2.3 (Chapters: 2.3.1., 2.3.2., 2.3.3., 2.3.4., 2.3.5., 2.3.6., 2.3.9., 2.3.10., 2.3.11., 2.3.12., 2.3.13., 2.3.14).

good history, field visits, detection and recognition of the clinical sings, necropsy findings, and examination of the samples collected in specialized laboratories (Fulton, 2013).

Toxics Found in Feed and Water

Mycotoxins

Mycotoxins were reviewed in the section of fungal diseases.

Biogenic amines and plant toxins

Biogenic amines, such as gizzerosine, are derived from overheated fish meal. Gizzerosine causes gizzard erosion syndrome. An example of a plant toxin is found from the unselected strains of rapeseed that contains erucic acid, which causes anemia and cardiomyopathy.

Nutrient additives

Some examples of poisoning caused by an excess of vitamins and elements (such as iron, zinc, calcium, sodium, etc.) were briefly described in the section of nutritional disorders.

Coccidiostats and other therapeutic drugs

Toxic coccidiostats in poultry include polyether ionophores, such as monensin, lasalosid, salinomycin, narasin, and maduramicin. These ionophores are characterized by the induction of myonecrosis in the skeletal muscles and occasionally the myocardium.

Sulfonamides are used to treat several infectious diseases; however, their therapeutic indices are very narrow, making likely an overdose. Sulfonamides induce vitamin K deficiency and consequently produce anemia, multifocal hemorrhages, jaundice, and bone marrow depression (Fulton, 2013).

Table 2 List of diagnostic methods and sample selection for the most important notifiable bacterial diseases of poultry

Methods of diagnosis for bacterial-origin poultry and avian diseases

Infectious agent	*Samples of choice*	*Serological techniques – Immune status*	*Etiological diagnosis – Identification of the agent*
Fowl typhoid and pullorum disease: *Salmonella*	● Aseptically taken samples of tissues (spleen and liver), intestinal (cecal tonsil) or cloacal content, eggs, embryos, oviduct, fecal droppings and cloacal swabs, and hatcher debris	● Rapid whole blood plate or serum agglutination test	● Culture (MacConkey agar, xylose lysine, brilliant green agar, Rappaport–Vassiliadis soya, etc.) and biochemical test (API system for Enterobacteriaceae) ● PCR-RFLP
Fowl cholera: *Pasteurella*	● Bone marrow, lung, liver, spleen, gonads and heart blood, and caseous exudates	● Rarely used for diagnosis of Fowl cholera	● Culture (Blood agar, trypticase-soy agar, and dextrose starch agar) and biochemical test ● Somatic typing procedure using gel diffusion precipitin test ● REA
Chlamydiosis	● Live birds: pharyngeal and nasal swabs, intestinal excrements, and conjunctival scraping ● Dead birds: Inflammatory or fibrinous exudates (peritoneal or in organs); ocular and nasal exudates; impression smear of the liver; whole blood; and tissue samples of the kidney, lung, pericardium, spleen, liver, and colon contents or excrements	● ELISA, AGID ● CF test, modified direct CF test, latex agglutination, and elementary body agglutination	● Isolation in embryonated chicken eggs or cell culture ● Cytochemical staining of smears or immunohistochesmistry ● Conventional and real-time PCR, restriction length polymorphism, DNA microarray, and sequencing
Mycoplasma	● Live birds: choanal cleft, oropharynx, eyes cloaca, and phallus swabs ● Dead birds: nasal cavity, infraorbital sinus, trachea, air sacs, esophagus, joint cavities, and material of egg yolk or embryos	● RSA test ● ELISA ● HI test	● Culture in specific media ● Basic biochemical test (i.e., fermentation of glucose and failure to hydrolyze arginine) ● Immunofluorescent antibodies and immunoperoxidase test
Tuberculosis	● Liver or spleen tissue samples and bone marrow	● Tuberculin test ● Blood stained-antigen agglutination test	● Detection of acid-fast bacilli in smears or tissue sections from affected organs ● Culture (Lowenstein–Jensen, Herrol'd medium and other media) ● Typing methods: ELISA and HPLC ● PCR, multiplex-PCR, and PCR-RFLP

Abbreviations: AGID, agar gel immunodiffusion; API, analytical profile index; CF, complement fixation; ELISA, enzyme-linked immunosorbent assay; HI, hemagglutination inhibition; HPLC, high-performance liquid chromatography; PCR, polymerase chain reaction; PCR-RFLP, PCR-restriction fragment length polymorphism; REA, restriction endonuclease analysis; and RSA, rapid serum agglutination.

Paris, France: World Organisation for Animal Health, Section 2.3 (Chapters: 2.3.1., 2.3.2., 2.3.3., 2.3.4., 2.3.5., 2.3.6., 2.3.9., 2.3.10., 2.3.11., 2.3.12., 2.3.13., 2.3.14).

Pesticide Toxicoses

Insecticides

Chlorinated hydrocarbon insecticides, such as DDT, chlrodane, heptachlor epoxide, etc., are not found in farms nowadays as they are banned due to their prolong persistence, high toxicity, and carcinogenicity in animals and humans. Organophosphorus (OPs) insecticides have a cholinesterase-inhibiting action and some of them are specifically toxic to birds. OPs compounds, such as diazinon, fenthion, and parathion, cause locomotor and respiratory muscular weakness, dyspnea, and paralysis. Carbamate anticholinesterase insecticides (bofuran, methomyl, and bendiocarb) produce similar clinical signs to the OPs, but it is more acute with marked tremors and convulsions. Finally, another insecticide widely used is the pyrethroid (permethrin, cypermethrin, and deltamethrin); however, they are very secure and only rarely cause toxicity. Clinical signs of hyperactivity, tremor, and salivation are observed in the affected birds.

Rodenticides

Rodenticides used in poultry buildings comprise first-generation anticoagulants and the most widely used second-generation anticoagulants as well as other less commonly used rodenticides (sodium strychnine, cholecalciferol, zinc phosphide, and sodium fluoroacetate). First-generation anticoagulants include warfarin, coumatetralyl, chlorphacinone, and diphacinone that can induce a subacute hemorrhagic syndrome in birds, whereas second-generation anticoagulants (brodifacoum, bromadiolone, difenacoum, difethialone, and flocoumafen) are highly toxic and are related to mortality in raptors and owls.

Toxicoses from the air or litter

Ammonia toxicity is common in poultry exposed to wet litter. Ammonia causes poor food conversion and eye and lung lesions. However, an example of air pollutant that causes toxicoses in birds is carbon monoxide, which induces ataxia and dyspnea and bright red blood (Fulton, 2013).

Diagnosis

Each laboratory test has been developed to accomplish an objective, which may be to confirm or exclude a presumptive clinical diagnosis, to perform an epidemiological study, to certificate a health status, or to monitor responses to vaccination. All pathogens have their mechanism of induction of lesions and disease; therefore, this knowledge is valuable to adequately select which samples have to be chosen and which diagnostic methods can give you better information to your purposes. In this section were summarized the diagnostic methods used to diagnose all notifiable diseases of poultry (Tables 1 and 2).

Precision Agriculture: Irrigation

SA O'Shaughnessy, USDA-ARS, Bushland, TX, USA
C Rush, Texas A&M AgriLife Research, Amarillo, TX, USA

Published by Elsevier Inc.

Glossary

Conservation Reserve Program Land conservation program administered by the Farm Service Agency, whereby participating farmers receive a yearly payment to remove environmentally sensitive land from agricultural production and plant species that will improve the health and quality of the soil.
Deficit irrigation Applying (meeting) less than full crop evapotranspiration requirements.
Irrigation scheduling A scientific method of determining when to irrigate and how much water to apply.
Low elevation spray application An irrigation technique in which the spray plate is 30–60 cm above the soil surface.
Low energy precision application An irrigation method in which the spray plate hangs near the ground, or a canvas sock is attached to the end of a drop hose. Water flows through openings in the sock as it drags along the ground.
Prescription maps Instructions or coding to direct variable rate irrigation sprinkler systems as to where and how much to irrigate.
Remote sensing In agriculture, the noncontact sensing of plant canopy or soil to acquire information.
Thermography Thermal images produced by cameras that detect radiation in the infrared region of the electromagnetic spectrum. In agricultural applications, digital thermal images have been used to map crop water stress and phenotyping.
Variable rate irrigation Applying different rates of irrigation in different locations throughout a particular field.
Wheat streak mosaic virus A virus that is vectored by curl mite. Extensive infections have been experienced within wheat fields across the Central Great Plains region.

Introduction

The High Plains region of the North American Great Plains includes portions of Texas, New Mexico, Colorado, Oklahoma, Kansas, Nebraska, and Wyoming. In most of the region, the primary cropping system is a corn/wheat rotation, and because of irrigation from the Ogallala Aquifer and high solar radiation, this is one of the most agriculturally productive regions in the United States. Total corn acreage in the High Plains area that overlays the Ogallala Aquifer is approximately 14.3 million acres (5.67 ha), and 2.4 million acres (1 millon ha) of irrigated winter wheat are planted in this region each year (USDA and NASS, 2008). Much of this wheat is dual purpose, i.e., planted as winter forage for livestock as well as for grain production if winter and spring precipitation are adequate. Although the economics of this corn/cattle/wheat agricultural production system are dominated by the cattle component, the sustainability of the system is dependent on the cropping component, which with corn in the mix is dependent on irrigation in the semiarid High Plains environment. However, the economic sustainability of irrigated crop production in the High Plains is increasingly at risk. Widespread adoption of irrigation, high pumping rates, and limited recharge have resulted in a precipitous decline in the Ogallala Aquifer's water table. Furthermore, increased temperatures and drought, associated with climate change, only exacerbate these problems; hence, the sustainability of crop production in the High Plains, as currently practiced, is clearly at risk. This decline in crop production affects not only those who farm the land but also those living in rural communities that are economically dependent on agriculture-related economic activity (Almas *et al.*, 2004). The overarching challenge for High Plain's agriculture is to maintain economically viable crop productivity, in the presence of increasing abiotic and biotic stresses, with a continually decreasing amount of water.

In the High Plains, the major stabilizing force against drought has been, since the Dust Bowl of the 1930s, the advent of irrigation. Almost all irrigation in the High Plains is from the Ogallala Aquifer, and development of irrigation in this region significantly increased beginning in the 1950s and continued until the early 1970s when fuel prices caused a decline in irrigation. In an attempt to reduce the inherent risks associated with agriculture, farmers have developed and implemented practices to improve efficiency and productivity, and one of the most successful of these has been irrigation. Irrigation allows farming in environments that would not otherwise support crop production. Typically, irrigation results in significantly greater yields than nonirrigated crops and substantially reduces the overall risk of production agriculture. Over most of its area, however, the Ogallala is essentially a closed system with minimal recharge. The dramatic increase in water extraction for crop irrigation resulted in a significant decline in the water table; in some areas it was up to 50% reduction in saturated thickness (Colaizzi *et al.*, 2008).

In addition, with irrigated agriculture comes a new set of issues and potential challenges, including preservation of the water resource, abundance, and quality; high initial costs of advanced irrigation systems; application method, amount, and scheduling; nutrient management; and erosion control and disease management. Over the years, depletion of the aquifer has spurred development of better irrigation application technologies and a variety of methods to improve crop water use efficiency (WUE = economic yield per unit of water used by the crop) (Stewart *et al.*, 2010), including precision irrigation equipment and management methods. The focus of this article

is on precision irrigation strategies that have been implemented and others that are currently in development.

Need and Benefits of Precision Irrigation Management

Although precision agriculture as a collection of technologies aims to control a number of inputs for optimal farm productivity, precision irrigation management is a subset of this technology that focuses on site-specific delivery of required amounts of irrigation water to specified management zones within a field. Site-specific delivery infers spatial control of irrigation water, whereas required amounts refer to volumetric control of irrigation water. The main objective of precision irrigation management focuses on maximizing the benefit-to-cost ratio of irrigation. This includes goals of improving crop yield, crop quality, and water use efficiency by applying the appropriate amount of water when and where needed. By achieving these goals, precision irrigation management can help to reduce excessive irrigation, resulting in adverse environmental impacts from runoff or deep percolation, and address water resource sustainability at the farm and regional levels.

Not only is excessive irrigation wasteful and expensive, but it can also reduce soil aeration and provide a favorable habitat for soilborne pathogens, which may increase crop vulnerability to disease (Allmaras *et al.*, 1988; Carter and Johnston, 1989). Soils with high matric potential (wetter soils) are usually more conducive to the growth, reproduction, and spread of soilborne pathogens (Cook and Duniway, 1981; Cook and Papendick, 1970; Duniway, 1979). Some soilborne pathogens, and the diseases they cause, are favored by lower soil matric potential (drier soils) and associated plant water stress, for example, *Macrophomina phaseolina* and *Fusarium* spp., which cause root and stem rots in a number of crop species. For these reasons, root diseases are often the major biological constraint to profitable crop production in irrigated agricultural systems, even those in extremely arid environments. Thus, if a grower's standard irrigation practices are responsible for increased losses from diseases, then the potential exists to reduce losses by modifying those irrigation practices so as to neither under- nor overirrigate.

Excessive irrigation can also reduce yields by leaching nitrogen past the root zone, thereby increasing crop vulnerability to weed pressure. However, water deficits can retard plant development, reduce crop quality and yield, or even cause complete crop failure. Applying only the amount of water that a crop actually needs helps to alleviate problems associated with over- or underirrigation. Water requirements for healthy crops are dependent on climatological factors, crop species, soil texture, and developmental stage. To further complicate irrigation management, diseased plants or those infested with pests may show limited water or nutrient uptake, due to root or foliar damage. Therefore, in order to maximize its potential, precision irrigation must include decision support for determining the incidence and severity of diseased or pest-infested areas within a field, the estimated value of decreased yield potential (based on quantity and quality), and whether to continue or withhold irrigation.

Precision irrigation practices are still evolving, but these irrigation systems rely on the integration of scientific principles and methods, plant and soil water sensors, and mechatronics to address within-field variability. The term mechatronics was coined by an engineer from the Yaskawa company to describe the integration of power, electronics, and mechanical systems – using hardware, software, and network systems – for control or automation (Acar, 2010). The framework for precision irrigation management is a systems approach that uses mechatronics for precision irrigation delivery with the objective to optimize crop productivity or yield per unit of irrigation water applied (**Figure 1**). A primary challenge is to adapt decision support to variable crop needs in the field, over space and time.

Spatial and Temporal Variability

In addition to inherent physical variations in soil type, slope, aspect, and elevation, abiotic and biotic stresses may be responsible for heterogeneity of crop status across agricultural fields. Examples of abiotic stresses include nutrient deficiencies, water stress, extreme temperatures, high winds, hail, and chemical damage. Biotic stresses are negative influences caused by other living organisms, and in production agriculture they typically refer to damage caused by insects, plant parasitic nematodes, disease, or weeds. In addition to being spatially variable, trends (progression of spread) and severity, or infestation levels in the case of biotic stresses, these stressors can vary over time and impact irrigation management decisions, for example, whether to irrigate, when to irrigate, or how much to irrigate. The ability to identify and analyze these stresses in crops is prerequisite to effective precision irrigation. Sensors and sensor network systems are used to detect spatial and temporal variability of plant and soil properties related to stress, and decision support algorithms are developed to determine the type of stress (disease or insect damage, too much or too little soil water, presence or absence of nutrient deficiency, which nutrient, and so on and so forth).

Spatial statistics can be used to augment information from sensors and predict patterns that manifest themselves in spatial variability. Methods for predicting a pattern at nonmeasured points using known values at neighboring points can generally be described as kriging (Matheron, 1963) or other interpolation methods. Kriging methods use semivariance statistics derived from a spatially related dataset of measured values in a field to interpolate a value for an unmeasured point based on the statistics and measured values of points surrounding the unmeasured point. Confidence intervals for the value at the unmeasured point(s) can also be derived with this method. Kriging has been used to map an integrated crop water stress index (CWSI) in a variably irrigated field (O'Shaughnessy *et al.*, 2011), which can lead to mapping potential yield based on crop stress indices.

Other models or datasets that have been developed to address variability within a field that could be applicable to decision support for precision irrigation include the model developed by Starr (2005) to scale the variance of soil water content measurements over space at any given time for

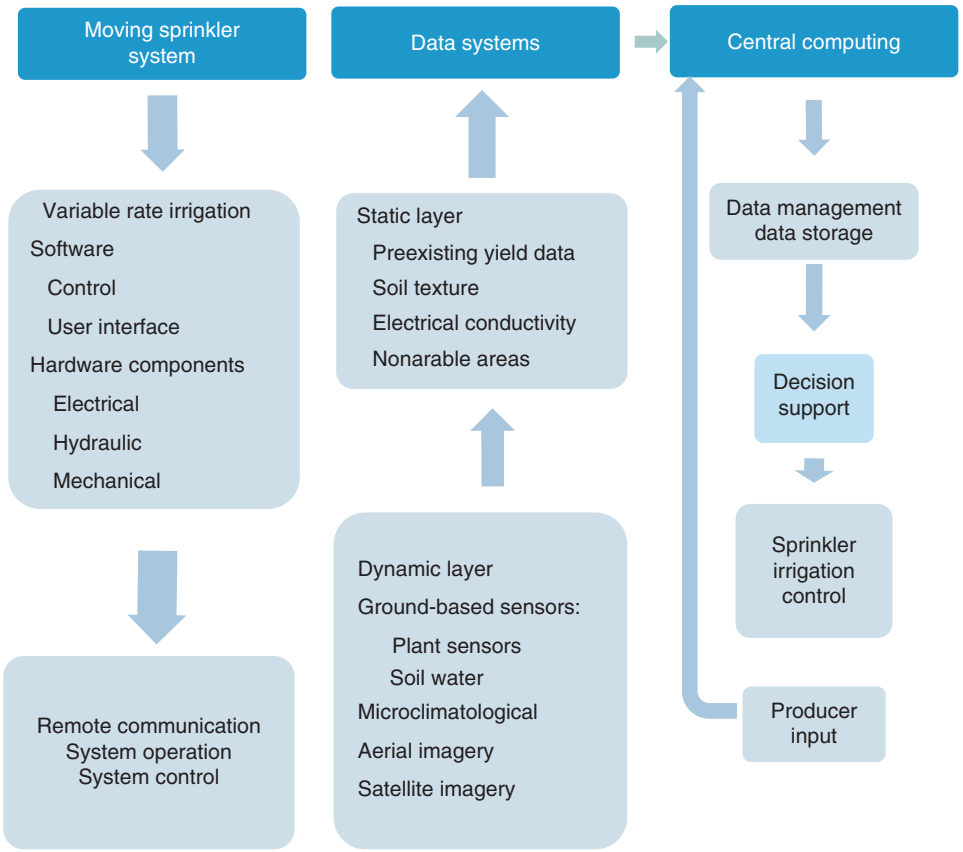

Figure 1 Overview of technology integration for precision irrigation management.

different points within a field and direct site-specific irrigation of potatoes. Also, mapping historical crop yields can offer insight into variability that is not obvious. Blackmore *et al.* (2003) developed trend maps to evaluate crop yields at the 'same point' over a number of years. This type of evaluation requires adjusting for year-to-year differences in climatic conditions. Machado *et al.* (2002) used biomass measurements (plant height and weight) to formulate irrigation scheduling for corn and predict yields. Workneh *et al.* (2009) formulated a structural time series model as a state space model to predict yield values as a function of disease intensity.

Identifying and monitoring spatial and temporal changes within a field is critical to executing precision irrigation. Initially, spatial variation within a field is used to configure boundaries for management zones and establish the configuration of irrigation zones. Over time, the detection or prediction of abiotic and biotic stresses within these management zones can allow decision making related to precision irrigation management throughout the growing season. The prediction of variability in time and space can be useful when monitoring crops by sensor network systems, but these can be limited by the number of available sensors (spatial limitation), such as soil water sensors. Similarly, there may be temporal limitations, as in the example of a moving sensor network system of infrared thermometers or passive spectral radiometers, whose useful measurements are made only during the daylight hours.

Physical Within-Field Variability

The optimal field for agricultural production has minimal slope, variation in soil type, and drainage requirements. Irrigation systems should be properly designed for the inherent topography of the field, soil and crop characteristics, and quantity and quality of the water supply. However, a number of physical variations usually exist within agricultural fields. These variations range from differences in soil texture, salinity, pH level, and topography to natural nonarable land attributes, such as roads, pump houses, waterways, and rock outcroppings (**Figure 2**). Differences in soil texture, restrictive layers, and depth can affect rooting and plant soil water extraction. Soil properties and water-holding capacities have been strongly associated with yield differences for crops (sorghum (Tolk and Howell, 2008); corn (Tolk *et al.*, 1999); wheat (Lawes *et al.*, 2009); soybean (Cox *et al.*, 2003); cotton (Ping *et al.*, 2008); and sugarcane (Johnson and Richard, 2005)). Precision irrigation systems can utilize georeferenced data and be programed to apply customized amounts of irrigation based on differences in soil texture or topography (e.g., Sadler *et al.*, 2005).

However, precision irrigation systems can be used to avoid irrigation of nonarable land areas in order to preserve structures, maintain access, or comply with environmental regulations. An example is irrigation application for animal production systems (e.g., dairies or hog farms) where the sprinkler system is used to apply liquid animal waste.

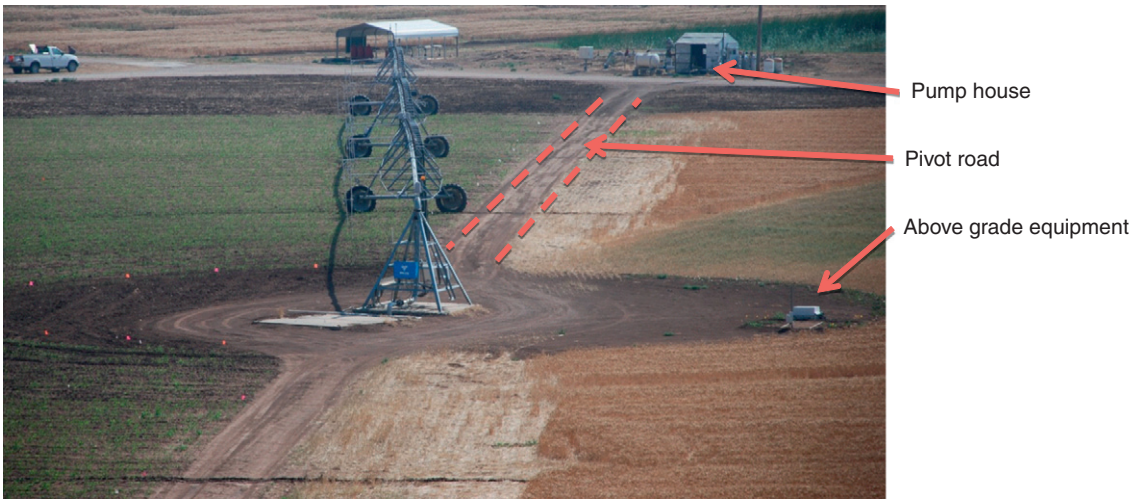

Figure 2 Center pivot field/examples of areas to avoid irrigating include pivot road, pump house, and above-grade equipment.

Precision irrigation systems can be used to insure compliance with setbacks from wells, surface water impoundments, or to avoid areas that are prone to nitrate leaching (Kranz *et al.*, 2012).

Other types of within-field variability may occur because of long-term agricultural practices, short-term farming mishaps (equipment failure causing overfertilization, overapplication of herbicide, chemigation spills, or over- or underseeding), or poor irrigation system design or maintenance (e.g., nozzle sizing and nozzle plugging). These latter types of imposed variations must be addressed first by changing farming practices, using proper engineering design, and performing ordinary maintenance. Precision irrigation management technologies cannot overcome extreme physical irregularities. Yet, this advanced technology could help to mitigate irregularities by maximizing water infiltration, reducing overwatering and deep percolation (leaching nutrients below the root zone), and minimizing runoff and run-on (Sadler *et al.*, 2000, 2002).

Prescription maps to address physical variations within a field are typically derived from soil surveys, electrical conductivity surveys (Lesch *et al.*, 2005), remote sensing images, historical yield maps, and as-built plot plans. These instructions are uploaded into the computer control panel of the irrigation system at the start of the irrigation season. These maps typically remain static throughout the cropping season. Although software is available to allow a producer to manually change the irrigation rates, the task can be time consuming and overwhelming for a novice user.

Implementation of Deficit Irrigation Schemes and Risk Management

As quality water resources for irrigation become scarcer, efficient use of water for maximum economic return and agricultural sustainability become more critical. Irrigation management strategies that are used to cope with declining and nonrenewable groundwater resources include deficit irrigation (DI) schemes. Precision irrigation management is a tool to implement these practices. DI, i.e., applying less than full crop evapotranspiration (ET) requirements, can be implemented by applying a percent of crop ET demands throughout the irrigation season. This scheme requires the estimation of crop ET, which is crop, soil (Tolk *et al.*, 1999; Tolk and Howell, 2012), and climate specific and is discussed in more detail later in this article. The second method of DI management is managed DI (MDI), which involves varying water application amounts according to critical growth stages (Doorenbos *et al.*, 1979). The goal in both DI and MDI is to maximize crop water use efficiency. DI practices have demonstrated sustained yields at levels that are economically feasible while reducing water use in many crops (Payero *et al.*, 2009). However, it is typical for farmers to use the 'conserved' water on other acreage.

The execution of DI implies knowledge of actual crop ET (ET_c), crop responses to the timing and severity of water deficits, and the economic impacts of yield reduction strategies (Pereira *et al.*, 2002). The key to DI management is to provide the appropriate amount of water to the crop to minimize damaging effects from crop water stress. Signs of crop stress include leaf wilt, scorched leaves, leaf senescence, abscission, pollination failure, and shoot and growth inhibition. Visual observations of water stress may come too late for the crop to help detect crop water stress or biophysical changes that signal advancement in crop growth stage. However, sensors can be instrumental in early detection of plant stress and in directing precision irrigation management.

If precision irrigation management is used to schedule DI yet avoid uneconomic reduction in yield quantity or quality, the system requires that crop stress and growth stage be assessed continuously throughout the growing season to avoid temporary severe crop stress that leads to uneconomic yields. Visual signs of crop water stress are specific to the crop species but in general can include leaf wilting, curling or burn, decrease in hue or brightness of crop canopy, retarded development, limited pollination, and reduced grain fill. In case of MDI, sufficient irrigation is applied at or just before critical growth stages (e.g., emergence to establish plant stand, at the onset of the reproductive stage through anthesis, and at grain fill). Sensors to help detect crop water stress or biophysical

changes that signal advancement in crop growth stage can be instrumental in directing precision irrigation management.

Methodology of Precision Irrigation

Fundamentals of Irrigation Scheduling

Precision irrigation management requires scientific irrigation scheduling to determine when, where, and how much to irrigate. Three main methods for scientific irrigation scheduling are: (1) weather-based crop ET (ET_c) calculations; (2) monitoring soil water status; and (3) monitoring plant canopy status. Algorithms that have been used to determine when to irrigate are numerous but are primarily based on the assessment of an established threshold; once the threshold is exceeded irrigation is triggered. Thresholds have been established for soil water depletion levels in the root zone or as thermal-based stress indices, such as the theoretical (Jackson *et al.*, 1981) and empirical (Idso *et al.*, 1981) CWSI, the Water Deficit Index (Moran *et al.*, 1994), and the Biologically Identified Optimal Temperature Interactive Console (BIOTIC, Patent No. 5 539 637 (Upchurch *et al.*, 1996) otherwise known as the time–temperature threshold method.

For healthy crops, the basic goal behind calculating the appropriate amount of irrigation to deliver, using precision irrigation management, is to meet deficiencies in crop water availability caused by shortages in precipitation and exacerbated by inadequate soil moisture storage capacities (Cuenca, 1989) for each management zone. Precipitation can be measured accurately with an electronic rain gage placed in close proximity to a specific field and measurements autologged and stored for retrieval by the irrigation controller. However, determining soil water content or energy potential properties that are representative of an entire field is challenging. Nonetheless, *in situ* soil water sensing and measurement (e.g., with neutron probe, tensiometers, capacitance, gravimetric core samples, moisture blocks, and time domain reflectometry (TDR)) have been used pervasively to decide when to irrigate (Evett, 2007). Some of these methods require manual measurements (neutron probe, gravimetric sampling, some capacitance, and TDR systems), which can be cumbersome, whereas other soil sensor systems, particularly those based on capacitance, can be sensitive to changes in temperature and bulk electrical conductivity (Evett *et al.*, 2012; Evett *et al.*, 2006; Schwartz and Evett, 2011), which are highly variable in time and space for many soils (Evett, 2007).

The most prevalent scientific method used to determine how much water a crop needs is based on estimations of crop water use or ET. If weather data are available (wind speed, air temperature, solar radiation, and humidity), reference ET (ET_0) can be calculated on a daily basis using the standardized American Society of Civil Engineering-Environmental and Water Resources Institute Penman–Monteith equation (Allen *et al.*, 2005). Crop water use is estimated as the product of ET_0 and the appropriate crop coefficient (K_c) (Allen *et al.*, 1998). Crop coefficients are species, region, and growth stage dependent. For a precision irrigation management system, the base station computer can collect microclimatological data from a nearby weather station and calculate ET_0 and ET_c using a predefined table of K_c values (as a function of growing degree days (Wang, 1960) or by relating K_c to normalized difference vegetative index (NDVI) values). ET estimates can also be derived from satellite- or aircraft-based imaging systems (with a thermal band) using surface energy balance algorithms, such as the two-source model (Norman *et al.*, 1995), surface energy balance models (Kustas *et al.*, 1994; Bastiaanssen, 1995), METRIC (Allen *et al.*, 2007), and RESET (Elhaddad and Garcia, 2011).

Soil water balance simulation models can be used to predict soil water content and therefore the amount of irrigation to apply. They range from simple models, such as a soil water budgeting process of irrigation scheduling (Fox *et al.*, 1993; KANSCHED, Rogers, 2009), to more complicated energy and water balance models, such as ENWATBAL (Van Bavel and Lascano, 1993; Evett and Lascano, 1993).

Soil water sensors or soil water balance models can be used in conjunction with the management allowable depletion method to schedule irrigation. This method uses the fundamental parameters of field capacity (fc) and permanent wilting point (pwp) properties, which are dependent on soil texture and bulk density, to develop a threshold for determining not only when to irrigate but also how much water to apply. An acceptable depletion level in the crop's root zone is established and then the percent depletion (%Depletion) is calculated on a daily basis:

$$\%\text{Depletion} = \frac{\theta_{fc} - \theta v}{\theta_{fc} - \theta_{pwp}} \times 100\%$$

where θ_{fc} is the soil water content at field capacity, θ_v is the current volumetric soil water content, and θ_{pwp} is the soil water content at the permanent wilting point (all in $m^3\ m^{-3}$). When the established threshold of percent depletion is reached, irrigation is signaled and the amount of irrigation is calculated as replenishment of soil water depletion to field capacity or to a percentage of field capacity (i.e., more or less than field capacity as indicated by factors, such as drainage rate and rate of soil water extraction by the crop). The base station computer of the precision irrigation system can manage daily calculations and provide decision support. Work by Thompson *et al.* (2007) illustrated a parallel method for irrigation scheduling and demonstrated how rates of soil water content changes measured by soil water sensors could be used to monitor an established lower limit of soil water change for irrigation management.

Precision irrigation management should establish fundamental methods for irrigation scheduling and then use sensor systems to refine irrigation scheduling and decision support. In addition to irrigation needs, decision support should inform the producer or irrigation manager about the health status of the crop, the growth stage, and if diseased, the severity level of the disease. Sensor systems and decision support are addressed in more detail in subsequent sections.

Irrigation Delivery

Field boundaries

To put site-specific irrigation management into practice, a field must be divided into geospatially defined areas or

management zones. Perhaps Vrindts *et al.* (2005) defined it best, "a management zone in a field expresses a subregion within a field that has a relatively homogeneous combination of yield-limiting factors, for which a single rate of a specific crop input is appropriate." Management zones delineated in a field are defined by geospatial coordinates, in addition to the attribute of interest. The basis for the boundaries of management zones within a field, as discussed previously, can be nonarable physical attributes, soil and topographical properties, historical crop yield data, etc. or a combination of datasets. For example, Schepers *et al.* (2004) used spatial data layers of bare soil brightness, elevation, soil bulk electrical conductivity, and crop yield data to characterize spatial variation in soil chemical properties and grain yield patterns.

Irrigation zones

The size of an irrigation zone may be limited by the design and flexibility of the irrigation system. The flexibility and resolution of a precision irrigation system are defined by the number of zones capable of being controlled and the width of those zones (O'Shaughnessy *et al.*, 2013). For moving irrigation systems, the minimum width of a management zone is determined by the number of drops or nozzles within an individually controlled set (e.g., under the control of a single solenoid valve), whereas the length could be determined by the pattern of variability in the direction of the traveling sprinkler or the length of the zone in the case of subsurface drip irrigation. For sprinkler irrigation systems, precise applications depend on wind speed and on the overlap from the wetted sprinkler patterns between management zones irrigating at different rates along the sprinkler lateral and in the direction of sprinkler movement when irrigation rates change. Low energy precision application (LEPA) drag socks (Lyle and Bordovsky, 1983; **Figure 3(a)**) offer perhaps the best method for precise irrigation application, followed by low elevation spray application (LESA) (**Figure 3(b)**).

In case of moving irrigation systems, variable rates of water can be applied by either speed or nozzle set control. By increasing the speed of a moving sprinkler irrigation system over a specific area, less water is applied; by decreasing the speed over the same area, more water is applied. Speed control is limited in that it only allows application rates to be varied in the direction of sprinkler travel but not along the sprinkler lateral. Nozzle set control, however, affords variable water application rates in both the direction of sprinkler travel and along the lateral pipeline. The benefit of speed control alone is that a limited amount of additional hardware is required for implementation. However, the limitation is the inflexibility to address variability along the length of the sprinkler lateral.

Irrigation machinery

The first commercially available mechanized irrigation systems were introduced in the United States in 1954 by Frank Zybach and A.E. Trowbridge (Morgan, 1993). After purchasing the marketing rights, Valley Industries revised the design and put the center pivot sprinkler irrigation system on the market. Since then, other manufacturers, such as Zimmatic, Reinke, and T-L Irrigation, have developed self-propelled sprinkler irrigation systems, either center pivots (a lateral with one end anchored) or linear move systems (unanchored lateral moves). Traditionally, these systems were designed to apply water uniformly across a field while delivering a specific application depth.

In the 1990s, several research groups (Washington State University, University of Georgia-Tifton Campus, University of Idaho, and USDA-ARS locations in Ft. Collins, CO, Sidney, MT, and Florence, SC) developed variable rate irrigation (VRI) equipment to manage irrigation spatially (Sadler *et al.*, 2005). Related efforts occurred at the USDA-ARS location in Bushland, TX (drip irrigation zone control, Evett *et al.*, 1996), which was controlled using plant status feedback based on IR thermometry, and at the Texas A&M AgriLife research location at Halfway, TX (center pivot speed and sprinkler set control, Bordovsky *et al.*, 1992). The first commercially marketed VRI package was jointly developed by the University of Georgia, and FarmScan (Hobbs and Holder, LLC) (LaRue, 2011). Key components for these new systems included: (1) hardware and software integration for mechanized control, (2) the incorporation of a global positioning system (GPS) receiver for navigation or spatial control, and (3) a programmable logic

(a) (b)

controller to operate and synchronize the pulsing of the sprinkler banks. Research work by Evans *et al.* (1995), McCann *et al.* (1997), Dukes and Perry (2006), Sadler *et al.* (1996, 2000), and King *et al.* (1995) sought to work through the complexities of integrating hardware into the existing moving irrigation systems. The objective was to deliver variable rates of irrigation along the sprinkler lateral and in the direction of sprinkler movement.

The following description covers only VRI systems for moving sprinkler systems. Computer hardware and software systems enable the overall control of the irrigation delivery hardware. VRI systems must have a control panel, consisting of a computer module that is capable of receiving and sending data regarding the operation of the irrigation system, and a controller. Software for VRI systems is the set of instructions for the controller, which manages the variable rate delivery of water per management zone as the sprinkler moves across the field. System management also involves the use of GPS data to map the system position relative to management zones so that system speed and nozzle sets (Figure 4(a)) can be controlled. In case of control via values that pulse nozzle flows, the synchronization of zone 'On' and 'Off' time is important to prevent water hammer or the system pump from shutting down due to low water pressure. The third purpose of the VRI software is to provide a graphical user interface (Figure 4(b)), to allow easy uploading of instructions by a producer, and verification of spatial instructions.

The combination of hardware and software allows site-specific irrigation scheduling customized for a particular field (Figure 4(c)); however, the prescription map is considered static if it is uploaded a single time and used throughout the growing season for irrigation scheduling. Initial prescription maps are generally based on inherent physical variability within a field, such as soil texture, salinity, pH, nonarable areas, and topography, as mentioned previously. For producers to address temporal variability, such as abiotic or biotic stress, prescription maps must be dynamic or modified throughout the growing season to address temporal changes.

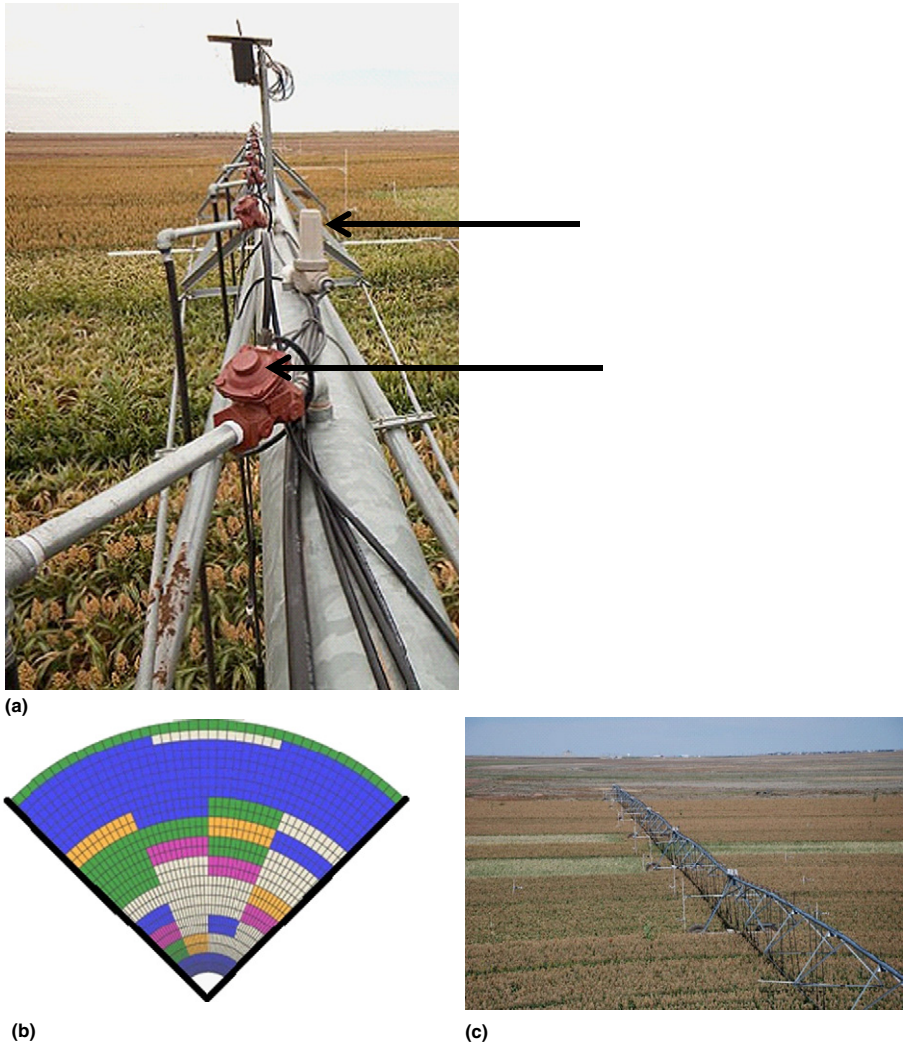

Figure 4 (a) Commercial variable rate irrigation (VRI) system mounted onto a center pivot irrigation system, (b) prescription map built with commercial software, where the different colored sections represent different levels of irrigation, and (c) irrigation field study with irrigation treatment plots established with a VRI system.

Dynamic instruction sets require the use of sensors and sensor network systems to detect the location of within-season variability over time and algorithms to decide where, when, and how much to irrigate or whether to withhold irrigation.

Sensors for precision irrigation management

Although major irrigation companies are now providing easy-to-use soil water and microclimatological sensors that provide information to the producer about the field environment, there are only a few precision irrigation systems that exist with sensors and algorithms fully integrated with the irrigation machinery to control irrigation scheduling. These advanced systems are used in research. Examples include an *in situ* sensor network system of soil water and thermocouple sensors to control the irrigation scheduling of a linear move irrigation system (Kim *et al.*, 2009) and center pivot irrigation systems using wired (Peters and Evett, 2004, 2008) and wireless (O'Shaughnessy *et al.*, 2012) sensor network systems of infrared thermometers to control irrigation scheduling using plant feedback methods.

Infrared thermometers assess a small portion of a field at any one time. However, Wanjura *et al.* (2004) demonstrated that when canopy size is sufficient to overcome the contributions of soil background, canopy temperatures measured from a small area by infrared thermocouples were comparable to those from a larger area viewed by a thermal scanner. If the infrared thermometers are mounted onto a moving irrigation system and are continuously collecting data, thermal information can be provided over space and time (Sadler *et al.*, 2002) and used to control irrigation (Peters and Evett, 2008). Continuous crop monitoring allows the assessment of temporal variation of crop water stress within a field. For example, O'Shaughnessy *et al.* (2011) documented the temporal trend of an empirical CWSI in a cotton field for the duration of an irrigation season and demonstrated its relationship to seasonal crop yield.

Both abiotic and biotic factors can induce stress in a plant, thus affecting transpiration rate, crop water use, leaf color, morphology, and crop density, each of which, in turn, affects the optical properties of the canopy (West *et al.*, 2003). To differentiate between abiotic (such as water stress) and biotic stresses (such as disease or insect infestation), it can be useful to outfit a precision irrigation system sensor network with more than one type of sensor. The incorporation of multiband optical sensors could provide timely detection of a crop disease or pest infestation within a field. Plants suffering from severe levels of disease are easier to detect than those beginning to suffer from early effects. The challenge is to discriminate healthy plants from those suffering from early, or less severe, levels of stress.

Digital imagery

Digital imagery has the advantage of providing data in a format that can be viewed and more easily validated. Digital images (visible, infrared, and hyper spectral) are processed using various methods that separate the image into pixels and then transform the spectral intensity in the various bands within a pixel to produce information related to plant status. For example, the red, green, and blue (RGB) components of each pixel of interest can be transformed into a more meaningful representation (**Figure 5**).

Since the 1990s, it has been known that thermography could detect plant disease earlier than visual observation could (Balachandran *et al.*, 1997). Aerial thermal imagery has been used to assess the heterogeneity of plant stress in orchards, vineyards, and over cotton fields. Falkenberg *et al.* (2007) demonstrated that images from a thermal infrared camera were able to detect biotic (root rot) and abiotic stress (drought) in cotton, using a camera with GPS and GIS capabilities. Unfortunately, thermographic images do not contain enough data to differentiate between such stressors. Data from thermal images enable the formulation of large area maps that indicate the location of water-stressed crops. Gonzalez-Dugo *et al.* (2013) extracted single tree crown temperatures from imagery using automated object-based methods to exclude mixed pixels of soil and vegetation. Ben-Gal *et al.* (2009) measured average tree canopy temperature with a thermal camera to calculate a theoretical and empirical CWSI over trees irrigated at different levels of potential ET. Aerial thermography has also been used to spatially map the water status of cotton (Alchanatis *et al.*, 2010) and vineyard plants within a field and then develop maps with leaf water potential levels for irrigation scheduling (Cohen *et al.*, 2005).

Visible imaging sensors are less costly than their thermal infrared counterparts and have the advantage of assessing color or color intensity using the RGB components of pixels. Commonly available visible imaging sensors are also sensitive to the near-infrared and ultraviolet light if left unfiltered. Visible imagery has been used to identify visual symptoms of plant disease remotely (Camargo and Smith, 2009), identify weeds (Tellaeche *et al.*, 2008; Burgos-Artizzu *et al.*, 2010), and distinguish vegetation from soil (Zheng *et al.*, 2009; Xue *et al.*, 2012). Digital images could be useful for decision making in precision irrigation management, if image processing is automated.

Spectral reflectance measurements

Optical sensors include nonimaging spectroradiometers, either multispectral radiometers (e.g., Crop Circle, CropScan, and Exotech) that provide reflectance measurements from a few bands or hyperspectral radiometers that have a broad spectral range (typically 400–1050 nm) with fine resolution (e.g., 1.4 nm). Radiometers are often augmented with a GPS unit to provide georeferenced data and are then useful for assessing spatial variability. Changes in canopy reflectance in healthy green plants are greatest in the near-infrared region (NIR), due to an increase of biomass and light scattering, whereas the visible region shows less seasonal variation (Hatfield *et al.*, 2008). Spectral reflectance in diseased or pest-infested plants (Yang *et al.*, 2009) is generally reduced in comparison with healthy plants, especially in the NIR region. One of the most useful vegetative indices (ratio of reflectance bands) is the NDVI (Rouse *et al.*, 1973):

$$(\mathrm{NIR} - \mathrm{Red})/(\mathrm{NIR} + \mathrm{Red})$$

where NIR is reflected radiation in the near infrared region (band width 790–1000 nm) and Red is reflected radiation between approximately 650 and 780 nm. This vegetative index

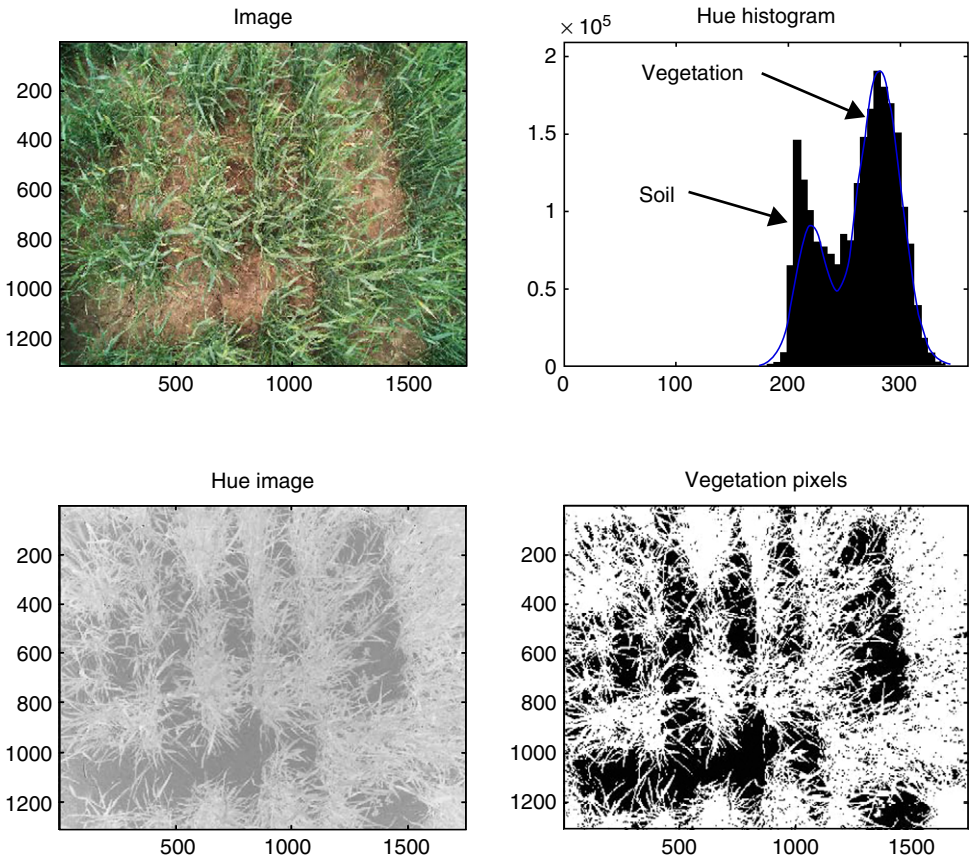

Figure 5 Digital visible image segmented by hue values calculated from red–green–blue components of the pixels of a digital image. Hue values were then separated into soil and vegetation using the expectation maximization algorithm (Moon, 1996).

has been used extensively to estimate plant canopy cover and crop coefficients for Et_c estimation (Hunsaker *et al.*, 2003, 2005). NDVI can also serve to indicate the presence of nitrogen and water stress. Plant *et al.* (2001) found the spatiotemporal pattern of NDVI-reflected stress factors and was approximately coincident with the onset of measurable water stress. Other vegetative indices have been used to estimate crop yield and to detect patches of weeds, disease, and insect infestation. Rumpf *et al.* (2010) demonstrated that vegetative indices from a hyperspectral reflectance instrument were able to discriminate between healthy sugar beet leaves and diseased leaves with an accuracy of 97%. They also confirmed presymptomatic detection of plant diseases with accuracy between 65% and 90%, using a support vector machine classification method and eight spectral indices as parameters (support vector machines are supervised learning models used in machine learning with associated learning algorithms to analyze and classify data). More recently, airborne hyperspectral imaging was used by Garcia-Ruiz *et al.* (2013) for early detection of citrus greening (Huanglongbing), which affects citrus production worldwide. Although data regarding crop canopy cover and crop status are available from satellite- or aircraft-based sensors, there is still the need to overcome the drawbacks of inadequate spatial and temporal resolution of the data, particularly in the case of satellite data (Ha *et al.*, 2013). Downscaling algorithms (e.g., Anderson *et al.*, 2003), more frequent satellite passes, and cloud computing may facilitate the integration of satellite-based information with precision irrigation management.

A requirement for complete precision irrigation management is to use sensors in a manner that provides information over the whole field. Therefore, any *in situ* or ground-based sensors should be wireless to reduce cost and maintenance (required for wired systems) and to prevent interference with farming equipment and tasks. If sensors are mounted onto moving irrigation systems, two sensors should be installed on opposite sides of each management zone, the sensors should face each other to reduce sun angle effects, and be oriented toward the canopy at an oblique, not nadir, downlooking angle to reduce effects of soil background. In case of drip irrigation/sprinkler for orchards, the wireless sensors should be located over representative areas within each specific management zone. Although images from aerial and satellite platforms are able to provide data over large areas, the images will need to provide adequate resolution to detect spatial variability within a single field. For all sensors and sensor network systems, access to useable data must be timely to meet irrigation scheduling requirements.

Algorithms

Algorithms for precision irrigation management should control an irrigation system so that it responds to within-field variability caused by abiotic and biotic stresses over the length of an irrigation season in an optimal manner (maximizing the

benefit-to-cost ratio of irrigation). Algorithms can be procedures or mathematical models to interpret data and provide decision support for sprinkler control and irrigation scheduling. Automatic control involves system input and feedback. Feedback for precision irrigation scheduling must provide a mechanism, process, or signal that is looped back into the irrigation system to control the timing and amount of water applied. In a closed-loop system for irrigation scheduling, a controller uses information from any number of inputs (microclimatological, soil matric potential, soil water content, canopy temperature or reflectance, or simulation models) and assesses the results of previous actions of the system to calculate the next action. If feedback is based on a prediction, for example, a rainfall event, the control is termed 'feed-forward.'

Kim *et al.* (2009) used a closed-loop feedback system to control the movement and irrigation scheduling of a commercial variable rate linear move system. Feedback control was established using a distributed network of soil water sensors. Sensors were strategically placed in a field mapped with a soil bulk electrical conductivity-sensing system. Irrigation was initiated when soil water deficits reached a preestablished threshold. Another closed-loop plant feedback method, the CWSI and Time Threshold (CWSI-TT) algorithm, was used to control irrigation scheduling of a center pivot outfitted with a VRI system (O'Shaughnessy *et al.*, 2012). In addition to irrigation control, the algorithm was used to control crop water use efficiency of grain sorghum hybrids. The algorithm for the CWSI-TT (based on the theoretical CWSI (Jackson *et al.*, 1981)) required scaling a remote one-time-of-day canopy temperature with a reference temperature measured throughout the day to estimate the diel temperature of the area represented by that remote location (Evett *et al.*, 1996 as implemented by Peters and Evett, 2004). The scaling algorithm allowed not only estimation of a diel temperature for a remote location but also comparison of canopy temperature for a large-scale area at the same time of day. This information can provide spatial and temporal CWSI maps over an irrigation season (O'Shaughnessy *et al.*, 2011), and it can be used to estimate seasonal grain yield. The algorithm for plant feedback irrigation scheduling included the use of varying threshold levels of the CWSI to initiate irrigation (**Figure 6**). Once a signal was generated, the irrigation amounts were always the same, i.e., twice (a function of irrigation frequency) the daily peak crop water use. The theory was that greater threshold values would result in less frequent irrigation, resulting in a controlled soil water-deficit condition (O'Shaughnessy *et al.*, 2012). The secondary calculation of crop water use (ET_c) was to enable irrigation for prolonged periods of cloudy skies for which infrared temperatures would not indicate crop water stress.

Model prediction or feed-forward control methods have been used extensively in simulations for precision irrigation control. Examples include the integration of crop development models with predictive control algorithms, including the VariWise framework (McCarthy *et al.*, 2010) and algorithms that model water dynamics in the soil–plant–atmosphere continuum, as used by Romero (2011) for controlling irrigation in almond orchards. These algorithms use historical measured data input streams, such as microclimatological data, soil water content, plant growth stages, and fruiting parameters in order to predict an outcome. The optimized outcome becomes the decision-making factor. Predictive methods are important because combined frameworks are needed to accomplish robust precision irrigation management. Such systems are data intensive and complex. Nonetheless, this type of arrangement has all the components of a supervisory control and data acquisition system and is on the cusp of commercialization.

For precision irrigation management in production agriculture, Romero *et al.* (2012) suggested the combination of feed-forward, feedback, and mathematical models to provide advanced irrigation control. Casadesús *et al.* (2012) developed a feed-forward irrigation-scheduling algorithm for tree crops based on the combination of microclimatological, plant, and soil water sensors. The integration of sensors to detect biotic stresses will expand the above algorithms and enable decision support to either continue or withhold irrigation. Finally, it should be noted that whatever the algorithm or combination of algorithms is, decision support procedures can allow producer interaction or they can be completely automated.

Information Technology for Remote Monitoring, Data Access, and Decision Making

Maintenance and oversight of the operation of precision irrigation machinery and sensor network systems require remote monitoring by wireless technologies. These technologies include fixed location systems, such as point-to-point microwave and stationary satellite systems, which generally operate at high baud rates. There are also near-fixed systems, local area network (IEEE802.11, 2012), and personal area network systems (Bluetooth, IEEE802.15.1, 2005; and Zigbee; IEEE802.15.4, 2011) that provide limited mobility over shorter transmission paths. Finally, wide area mobile systems, such as paging and cellular, provide extended mobility (Moring, 2004).

At present, the majority of commercially available remote monitoring systems focus on equipment operation and malfunctions. However, agricultural researchers and a limited number of commercial companies specializing in agricultural applications (e.g., CropMetrics and SmartCrop) are beginning to integrate plant sensors, for example, infrared thermometers (O'Shaughnessy and Evett, 2010), RFID tags (Sjolander *et al.*, 2010), soil water sensing (Kim *et al.*, 2009), and microclimatological networks with irrigation systems for precision irrigation control. With the addition of wireless field-based sensor systems, it becomes necessary to access data remotely to evaluate connectivity, troubleshoot network system issues, and perform quality analysis and quality control on the data. In the future, it is more likely that central data storage and sharing will be the basis for combining satellite and aerial imagery to provide for optimal irrigation scheduling and control. The advent of cloud-based computing, a term used to express services that are commoditized and delivered (Buyya *et al.*, 2009), could facilitate faster computing time and larger data storage.

Precision Irrigation for Disease Management

In many regions of the United States, particularly those areas where irrigation water is scarce, irrigation with center pivot

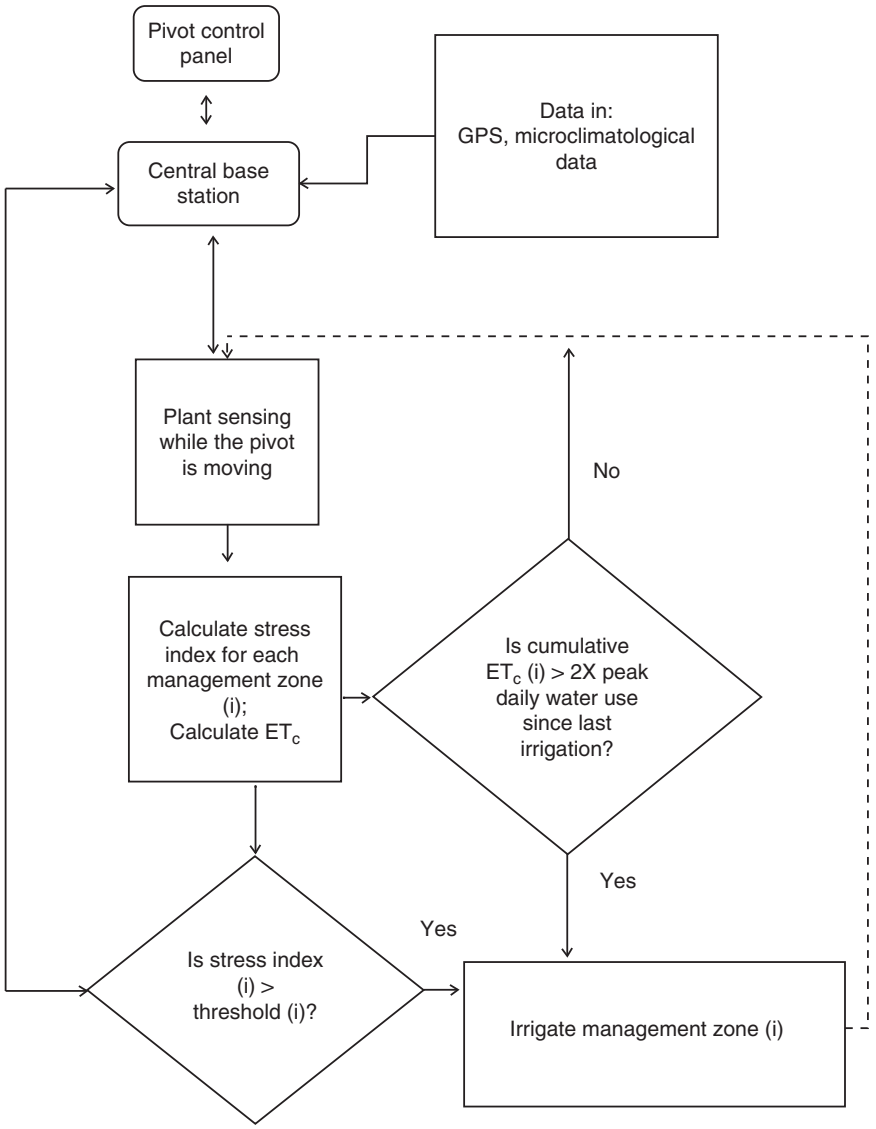

Figure 6 Process for precision irrigation scheduling using a plant feedback system; input from network of infrared thermometers and microclimatological data. ET_c, Estimation of crop evapotranspiration.

irrigation systems has largely replaced furrow irrigation. Many producers in areas of high evaporative demand still over-irrigate because they fear 'getting behind' and not being able to supply the crop with adequate water. In these situations, farmers often turn on the pivot and let it run continuously. As a result, soils in these fields may remain constantly wet, creating conditions conducive to disease. Fahnert (1999) conducted a study to evaluate the effects of different irrigation amounts and frequency on incidence and severity of disease in sugar beet. A center pivot system was equipped to deliver varying percentages of the normal amount of water applied at the usual (farmer determined) frequency or with on/off valves that allowed the grower to irrigate at different frequencies. At harvest, the final number of harvestable beets, disease incidence and severity, and root yield and quality were determined. With regard to disease incidence and severity, irrigation frequency had a greater impact than total irrigation. Reducing irrigation frequency to half the norm resulted in significantly less disease, higher percent sucrose, and higher root yields than beets irrigated at the usual frequency. After this and a number of other studies, there was no question that irrigation could affect disease incidence and severity, but it was also clear that disease incidence and severity could be reduced by improved irrigation management, i.e., applying the correct amount of water at the right time and frequency.

Framing a New Question

In all irrigated agricultural cropping systems, it is imperative for farmers to understand how irrigation management can impact disease, crop water use, yield, and quality of their crops. In many areas of the United States, however, high quality water for irrigation is becoming increasingly scarce and expensive to apply (McGuire, 2007). In some instances,

disease incidence and severity may not be directly impacted by irrigation amount or frequency, but if disease is present in the field, the farmer must decide whether the cost of applying additional irrigation (both in terms of actual expense and also depletion of a limited resource) is economically and environmentally sustainable. This decision is greatly complicated when the disease is progressive and increases in both incidence and severity over time. Wheat streak mosaic virus (WSMV) is a prime example of such a disease.

Development of an Economic Threshold for Site-Specific Variable Rate Irrigation of Fields with Wheat Streak Mosaic

In the Southwestern Great Plains, which includes parts of Texas, Oklahoma, Colorado, and Kansas, disease caused by mite-vectored viruses is the predominant biotic constraint to economically sustainable wheat production (Appel *et al.*, 2007; Burrows *et al.*, 2009). A recent wheat virus survey revealed that WSMV and Triticum mosaic virus were both common throughout the Great Plains, especially in the Texas Panhandle (Burrows *et al.*, 2009). These viruses are vectored by the wheat curl mite (*Aceria tosichella* Keifer) and cause significant reductions in root growth, WUE, and grain yield and quality (Price *et al.*, 2010; Workneh *et al.*, 2010).

Factors that impact mite populations and subsequent disease development are poorly understood, but disease epidemics are typically associated with hot, dry weather conditions. In most cases, mites are introduced into recently planted wheat fields from patches of volunteer wheat, native pastures, or land taken out of production by the US federally funded Conservation Reserve Program and planted to grasses that serve as oversummering reservoirs for the mites. Disease first appears at the edges of fields and as mite populations increase, they are blown across the field over time. In this manner, WSM develops disease severity gradients across fields, typically with the most severe disease occurring near the edge of the field where mite populations and plant infections were first established, and gradually decreasing in severity with increasing distance from the edge. To quantify this disease severity gradient and its effect on plant–water relations, Workneh *et al.* (2010) used a handheld hyperspectral radiometer to measure reflectance at 555 nm, which correlates well with visual disease severity ratings. These severity ratings were taken at regularly spaced points along the disease gradient when plants were at Feekes Scale 8, and gravimetric soil water content and plant yield parameters were also taken at each point. Plants from more than 90% of the sampled points tested positive for WSM, but disease severity ratings were strongly correlated with distance from the initial infection locus at the edge of the field. Additionally, as distance from the edge increased, disease severity decreased (indicative of later infections), soil water content decreased, and WUE and grain yields increased. Although most of the plants in this field eventually became infected, those infected later in the season were still capable of producing good grain and forage yields, and therein lies the management problem for farmers. The progressive nature of WSM makes it difficult for producers to know whether additional crop inputs, such as fertilization, pesticides, and multiple spring irrigation, are economically feasible.

Currently, most farmers manage their irrigated wheat fields as a single unit, applying inputs uniformly across the field, despite recognized variations in yield potential. The recent advances in irrigation technology discussed above may soon allow farmers to modify their current center pivot irrigation systems for site-specific variable rate applications. Such systems would be ideal for differentially irrigating wheat crops affected by WSM. However, in order to maximize the potential benefits of site-specific VRI of diseased wheat, an economic threshold for WSM is required.

Most studies relating disease severity of WSM to final yield have relied on disease ratings made relatively late in the season, well after the majority of inputs have been made. What is needed is a risk assessment model that could take disease severity ratings in early spring, before the majority of inputs have been applied, and predict yield potential for the entire field. Unfortunately, such a model does not exist, and due to the lack of knowledge concerning ecology and epidemiology of WSM, it would take years to develop such a model. However, continuous monitoring for disease severity using wireless pivot-mounted or stationary remote sensing devices potentially could provide timely detection and quantification of disease severity and provide a sensitive 'trigger' for site-specific irrigation.

As an alternative to ground-based imaging, satellite imaging has shown promise for quantifying the incidence and severity of WSM and the potential to apply this information for irrigation decision support. A study was conducted to evaluate Landsat 5 TM imagery for detection, quantification, and mapping of WSM in irrigated wheat fields. Imagery was acquired biweekly, beginning in early March, and diseased wheat was separated from healthy wheat using a subpixel classifier with $>91\%$ accuracy (Mirik *et al.*, 2013). In this study, early stages of WSM in which symptoms were just beginning to develop were not included in the classification, but based on previous studies (Workneh *et al.*, 2009, 2010), infections first appearing in mid-April or later had minimal impact on final yield. Although the 30 m pixel size of Landsat 5 imagery would restrict its usefulness for detection of some diseases, it was adequate for detection of WSM in commercial irrigated fields; moreover, 30 m would represent a reasonable irrigation management zone. The ease in acquiring low-cost, large-scale, biweekly images that can be used to accurately detect, quantify, and map WSM in commercial wheat fields qualifies this technology for potential use in site-specific irrigation of diseased wheat.

The incidence of WSM in large-sized pivot fields across the Texas Panhandle is one example for the application of precision irrigation management in production agriculture. It illustrates the need for site-specific irrigation to meet variable crop water needs of healthy and diseased wheat. The progression and changing levels of severity in WSM requires continuous crop status monitoring to provide spatial detection of disease and temporal information on severity level throughout the growing season. Algorithms factoring in disease severity level can provide decision support to farmers for irrigation scheduling of wheat that has the potential to produce economical yields or withholding irrigation in the case of severely diseased wheat. In this manner, irrigation management focuses on maximizing the benefit-to-cost ratio of irrigation.

Glossary

Conditional factor demand Input use, x_i, chosen for least-cost production of output, y, when input prices are $w_1,\ldots, w_n$: $X_i(y, w_1,\ldots, w_n)$.

Cost function Least amount of money needed to purchase inputs to produce a specified output level, y. When the prices of inputs are $w_1,\ldots, w_n$, the cost function is written $C(y, w_1,\ldots, w_n)$.

Production function Agricultural yield expressed as a function of the use of inputs, such as water, nitrogen, labor, land, and equipment. If the physical quantities of inputs are $x_1,\ldots, x_n$ and the physical quantity of output is y, then the production function is mathematically represented as $y=F(x_1,\ldots, x_n)$.

Profit function Maximum farm earnings net of production costs as a function of output price, p, and input prices, $w_1,\ldots, w_n$. Profits are total revenues from farming less total costs of farming; the profit function, π, is written as $\pi(p, w_1,\ldots, w_n)$.

Supply curve Profit-maximizing output level as a function of output price, p, and the prices of inputs, $w_1,\ldots, w_n$: $Y(p, w_1,\ldots, w_n)$.

Unconditional factor demand Input use, x_i, chosen for profit-maximizing production when input prices are $w_1,\ldots, w_n$ and output price *is* p: $X_i(p, w_1,\ldots, w_n)$.

The Basic Theory of Production

Production Functions

Production economics begins with the production function – a mathematical relationship between the inputs used for farming and the resulting output. The production function F is purely a technical relationship. It summarizes knowledge about the production process but implies nothing about the behavior of farmers or of markets.

Economists assume that the production function has several properties. First, output is nondecreasing in each input. That is, if use of one input increases, all other inputs held constant, then output should increase or, at least, not decrease. Mathematically, the partial derivative of F with respect to each input is nonnegative. In agriculture, it is possible that output will decrease if the input (such as fertilizer or manure) is applied excessively (first derivative becomes negative), but it is usually assumed that such applications are outside of the range of what farmers would use.

Second, each additional unit of input usually adds less to output than the unit before, a phenomenon referred to as diminishing marginal product. Mathematically, the second partial derivative of output, with respect to that input, is nonpositive.

Third, production functions have constant or decreasing returns to scale. A production function has constant returns to scale if doubling all inputs doubles output. (Returns to scale are decreasing if doubling all inputs leads to less than a doubling of outputs. They are increasing if doubling all inputs leads to more than doubling of outputs.) When output is analyzed as a function of physical inputs, such as land and fertilizer, agricultural production functions can reasonably be assumed to have constant returns to scale. In other words, if a farm is doubled in size, output should double. Because, as farm size increases, farmers are often able to specialize and make better use of certain inputs (such as labor and machinery), the production function may have increasing returns over much of the relevant size range. In wheat farming, for instance, the ability to use large implements on large tractors makes it possible for a large farm to use less labor per unit of output than a small farm.

A production function with constant returns to scale can be written on a per-acre basis. That is, if x_1 is the number of acres, then $y/x_1=g(x_2/x_1,\ldots, x_n/x_1)$. A frequent way to analyze agricultural output is to write separate equations for per-acre production and for acreage in the crop. Acreage is assumed to adjust to changes in profits from one crop relative to profits from an alternate crop.

Pesticides and other damage-control agents do not behave like ordinary inputs in that they do not increase yields directly. Instead, they limit the reduction in yield from pests or other damaging agents. To reflect the difference between damage-control agents and other inputs, a production function can be specified as

$$y=f_1(x_2,\ldots,x_n)+f_2(x_2,\ldots,x_n)G(x_1)$$

where x_1 is the damage-control agent and $x_2,\ldots, x_n$ are other inputs. The function $G(x_1)$ is the proportion of the pest damage that is controlled by use of the input x_1; it has a range between 0 and 1. Any cumulative probability distribution function is a potential choice for a functional form for G. When damage is uncontrolled, the output is f_1. When it is perfectly controlled, it is f_1+f_2.

Cost Minimization

In most production processes, different techniques can be used to produce a given level of output. Irrigated crops, for example, can produce the same output with flood irrigation (more water and less equipment) or sprinkler irrigation (less water and more equipment). Economists assume that, for any specified level of output, firms choose the combination of techniques to produce that output at least cost. In the example above, if water were expensive relative to irrigation equipment,

 doi:10.1016/B978-0-444-52512-3.00121-2

sprinklers would be adopted. If water were inexpensive relative to equipment, flood irrigation would be used.

More technically, firms choose inputs, $x_1,\ldots, x_n$, to minimize the cost of those inputs, $w_1\times_1+\cdots+w_nx_n$, subject to the constraint that a given level of output, y, is achieved: $y=F(x_1, \ldots, x_n)$. Levels of input use chosen as a function of input prices and output are conditional factor demands, $X_i(y, w_1,\ldots, w_n)$. The cost function is $C(y, w_1,\ldots, w_n)=w_1\times_1(y, w_1,\ldots, w_n)+\cdots+w_nX_n(y, w_1,\ldots, w_n)$.

A conditional factor demand decreases as its own price increases. Effects of other input prices on this curve depend on whether inputs are substitutes or complements. For most inputs, increased output shifts factor demands out; these are termed normal inputs. Inputs whose use decreases when output increases are called inferior inputs.

Other facts about conditional factor demands are derived from economic theory as well. First, $\partial x_i/\partial w_j=\partial x_j/\partial x_i$. That is, the effect of the price of input j on factor i is the same as the effect of the price of input i on factor j. Second, they are characterized by homogeneity of degree 0, which means that doubling all prices with output held fixed does not change the input mix. This assumption implies that only relative prices (the ratio of each input price to one designated 'numeraire' input price) matter.

Profit Maximization

Each firm engaged in agricultural production supplies only a tiny fraction of the market for that product. No single farm can significantly affect market volume or market price. Such firms are called price takers. A reasonable approximation of their behavior is derived by assuming that they maximize profits. There are two steps to maximizing profits: deciding how much to produce and choosing inputs to produce that amount at minimum cost. Because the input decision problem is summarized in the cost-function analysis, the remaining problem for the firm is to choose the output level to maximize profits, which are revenues less costs, $py-C(y, w_1,\ldots, w_n)$. The y chosen to maximize profits yields the decision rule $Y(p, w_1,\ldots, w_n)$, called the supply function. The supply function gives the profit-maximizing level of output for any set of input and output prices. The profit function summarizes the output and input decisions in the same way that the cost function summarizes input decisions and is written as $\pi(p, w_1,\ldots, w_n)$.

Economic theory predicts that the supply function is nondecreasing in output price and nonincreasing in input prices. In practice, one expects that an increase in the output price will increase the quantity supplied, whereas an increase in an input price will decrease the quantity supplied. Finally, the supply function is homogenous of degree 0 in output and input prices. If all output and input prices double, production should remain unchanged. Thus, only relative prices matter.

The supply function from profit maximization can be substituted for y in the conditional factor demands. The resulting functions (which give input use as functions of input prices and output price) are termed unconditional factor demands, because they are no longer conditioned on output. Properties of the unconditional factor demands are the same as those of conditional factor demands.

Risk

Agricultural firms bear considerable yield and price risks. Weather, world demand conditions, government programs, and pest problems are a few sources of risk in agriculture. A better approximation of farm behavior than simple profit maximization includes a consideration of farmer attitude toward those risks and of the actions farmers can take to avoid those risks.

Risk-averse farmers are willing to take lower expected profits to lower the variability of their profits. Consider two possible outcomes for farm income: high income, H, which happens with probability λ, and low income, L, which happens with probability $(1-\lambda)$. A risk-averse individual prefers a certain income equal to the average, $\lambda H+(1-\lambda)L$, to the uncertain income stream. In fact, such an individual may be willing to take a payoff lower than $\lambda H+(1-\lambda)L$ to avoid the uncertainty.

Risk aversion can lead farmers to alter their practices in a number of ways. For instance, they may choose to spend more on inputs if they can reduce the uncertainty in crop yield. Instead of growing just the most profitable crop, farmers may choose to grow many crops in the hope that some crops will do well even if others do not.

Duality

Although it is most natural to think of the physical relationships of production being summarized in the production function, the same information is contained in the cost and profit functions because of their derivations from the production function. This property of cost, profit, and production functions is called duality. Its practical consequence is that all technical information about production can be recovered from the cost function (which depends on prices and output) or from the profit function (which depends only on prices).

Shepard's lemma

The problem of minimizing cost for given output makes direct use of the production function and leads to conditional factor demands. Those same factor demands can be found in a second way. The calculus can be used to prove that the derivative of a cost function with respect to input price is the conditional factor demand. Because the same input decisions are found either by working out the minimization problem, using a production function, or by taking the derivative of a cost function; these two functions contain the same information.

Hotelling's lemma

Just as conditional factor demands can be found directly from the cost function, unconditional factor demands can be found from the profit function. The derivative of the profit function, with respect to output price, is the supply function. The negative value of the derivative with respect to an input price is an unconditional factor demand.

Multiproduct Model

Most farm operations have more than one output. Hog farms often produce corn and soybeans, cotton farms tend to grow alfalfa, and farms in the developing world frequently include

several types of livestock as well as vegetables and grains. The formal analysis for such operations is an extension of the single-product analysis presented above. Instead of only one output, y, let $y_1,\ldots, y_m$ represent the m possible outputs. The multiproduct production function, H, is commonly written in an implicit form, such as $H(y_1,\ldots, y_m, x_1,\ldots, x_n)=0$. The cost function is $C(y_1,\ldots, y_m, w_1,\ldots, w_n)$; the profit function is $\pi(p_1, \ldots, p_m, w_1,\ldots, w_n)$; and so forth. With a suitable choice of functional form, these relationships can be used directly. Although there are examples of work at this level of generality, such as a study of expansion effects and substitution possibilities for Canada, there is a tendency, particularly among those interested in farm management, to place more structure on the problem.

The most common method of analyzing a multiproduct system is first to examine the production relationships of each activity (crop or livestock production) individually and then to examine the profit-maximizing choice of activities.

Farmers have many reasons for producing more than one crop. First, different soils may be suited to different crops. Second, if labor, capital, or other input requirements for two different crops are complementary, then both can be grown with the same inputs and greater production can be achieved with little increase in cost. Third, producing a variety of crops reduces risk, because factors that may cause one crop to fail may not be factors that will destroy another crop. Even if one crop is destroyed, the farmer can still earn profits from those remaining. Fourth, rotations may be desirable to control pests or maintain soil characteristics. Various programming methods, described below, can be used to solve this allocation of scarce resources among crops.

Estimating Production Relationships

The previous discussion has presented the economic theory of production. The next step in analyzing production relationships is data collection and analysis. Data collection and analysis are used to determine empirical production, cost, and profit functions and associated factor demands. These functions are used for policy analyses and farm-management recommendations.

Data Sources

Data derived from a range of sources can be used to develop estimates of production, cost, and profit functions. Some of these data sources are experimental, farm survey, county data, and cost and return estimates.

Experimental

Agronomic field trials provide data that include different input combinations and their resulting output. Examples include experiments to find responses of various crops to nitrogen, potassium, and water.

Farm survey

The U.S. Department of Commerce, Bureau of the Census, conducts a census of agriculture every 5 years. Every farmer in the US is asked information on their farm operations, including input applications, irrigation methods and amounts, acreage in different uses, size of farming operations, market value of assets and debts, and other areas. Every year as well, the National Agricultural Statistics Service of the U.S. Department of Agriculture surveys a subset of farmers and collects similar information for specific crops. The USDA Risk Management Agency collects extensive data needed to administer crop insurance programs; this data and similar data from private crop insurers is just beginning to see use. Other surveys are often conducted by researchers interested in specific issues or regions.

County data

The local government in most states in the US collects acreage, output, and value of output by crop for the major crops in each county. This information can be used to construct countywide agricultural land-use models.

Cost and return estimates

Land-grant universities in most states in the US estimate how much it will cost to produce a crop and what revenues to expect on a representative farm. These estimates are based on a standard set of inputs, management techniques, and level of output, determined by consultation with farmers and local crop experts, and with specified prices for inputs and output. They are used for a wide range of purposes, including determining whether an investment in a particular crop is worthwhile, examining the effects of alternative management practices on profits, estimating the value of land in production of a crop, and analyzing whether the costs on a particular farm are relatively high or low.

In addition, the U.S. Department of Agriculture conducts a Farm Costs and Returns Survey for a range of crops (including all crops involved in federal crop support programs) every 5 years. This survey reports how much, on average, farmers spend for production of each crop and how much they earn.

Statistical Techniques and Functional Form

Statistical estimation of crop production functions requires not only data on inputs applied and output attained, but also a class of assumed mathematical forms to relate the inputs and output. A class of functions is determined up to r numerical values, $\alpha_1,\ldots, \alpha_r$, called the parameters of the function. A choice of the form of the function $F(x_1,\ldots, x_n; \alpha_1,\ldots, \alpha_r)$ is necessary to conduct most analyses. Statistical techniques are used to determine the parameters that make the equation fit the data as accurately as possible.

Data never conform perfectly to a functional form chosen to approximate the true production function. Measurement error, omitted variables, and error in the choice of functional form all contribute to the imperfect fit. These discrepancies between actual yield and the yield predicted by a production function are called error terms, ε. The relationship between inputs and output is assumed usually to be of the form

$$y = F(x_1, \ldots, x_n; \alpha_1, \ldots, \alpha_r) + \varepsilon$$

This form means that, for each observation (year and farm, field, county, or state), the output for that observation is

related to the inputs for that observation plus an error term. Assumptions about ε, such as normality, lead to particular types of estimation.

A common choice for an agricultural production function is a quadratic function. With two inputs, the function is written as

$$y = \alpha_1 x_1 + \alpha_2 x_2 + \alpha_3 x_1 x_2 + \alpha_4 x^2{}_1 + \alpha_5 x^2{}_2 + \alpha_6$$

In this function, six parameters need to be determined by statistical techniques. Generalizations of the quadratic include higher-order polynomials, polynomials in square roots, and polynomials in logarithms (called translog).

As noted above, diminishing marginal product is commonly assumed in economics and commonly observed in reality. This assumption is incorporated by limiting the choice of forms (or parameters) to those that permit positive first derivatives and negative second derivatives. In addition to polynomials, the following functional forms (given for the two-input case) are frequently used and have these characteristics.

Mitscherlich	$y = (1-e^{\alpha_1 x_1})(1-e^{\alpha_2 x_2})$
Von Liebig	$y = \min(\alpha_1 x_1, \alpha_2 x_2)$
Cobb–Douglas	$y = \alpha_0 x_1^{\alpha_1} x_2^{\alpha_2}$
Translog	$\ln y = \alpha_0 + \alpha_1 \ln x_1 + \alpha_2 \ln x_2 + \alpha_3 (\ln x_1)(\ln x_2)$

Pope/Just Production Function

The Pope/Just production function generalizes the other functions described by including the possibility that different inputs have different effects on the variability of output. Let the function $g(x_1,\ldots, x_k)$ include only those k inputs that affect yield variability, either positively or negatively. The Pope/Just function is then written as

$$y = f(x_1, \ldots, x_n) + g(x_1, \ldots, x_k)e$$

where e is the error term. This generalization of the error term can be used to analyze situations where farmers use inputs that are relatively expensive but that reduce risk and reduce use of inputs that increase risk.

Estimation of Multicrop Production Functions

The estimation of individual production functions for each crop in a multicrop system is hampered by lack of data. Farmers often keep records of the inputs purchased for the whole farm, but they rarely keep records of which inputs were used for which crops. For instance, a farm might have records on the total purchase of nitrogen fertilizer and output of soybeans and corn but no records about the amount of fertilizer allocated between soybeans and corn. Without the allocation of the input between the two crops, it is not possible to determine directly the effect of changing fertilizer use on the production of either crop.

One solution is to use an aggregate function, with the underlying assumption that fertilizer is allocated optimally between the two crops. The added information from this behavioral assumption gives the problem enough structure to be solvable.

Statistical Techniques and Problems

The most common technique to determine the parameters, α_1, …, α_r, is to find the set of parameters that minimizes the sum over all observations of the error terms squared, ε^2. (The error term is squared to prevent positive and negative errors from canceling each other out without finding a good fit.) This method, called least-squares estimation, is used with an additive error term. Using the least-squares estimation, inputs are assumed not to be related to the error term and parameters that best explain the relationship between the inputs and output are found.

Another class of models are those in which the error term is assumed to be inside the function, such as $y=F(x+\varepsilon)$. For instance, the von Liebig function with two inputs, when the error term is incorporated, can be written as

$$y = \min(\alpha_1 x_1 + \varepsilon_1, \alpha_2 x_2 + \varepsilon_2)$$

A switching regression can be used to estimate the parameters of this function.

A requirement for consistent estimation of a production function by least squares is that inputs are independent of the error term. For instance, inputs may be related to planting, whereas the error term might consist largely of weather which occurs after planting has taken place. In this case, the assumption of independence is reasonable. In more managed agricultural systems, however, the input data available often violate this assumption. For instance, the number of pests, which is difficult to count, is an omitted variable and thus part of the error term. If pesticide inputs are applied after the pests are observed, then their use is correlated with pest presence and violates the independence assumption. Similarly, the amount of water applied often correlates with weather (a frequently omitted variable). This violation of assumptions leads to estimators with very poor statistical properties: the estimated parameters do not approach the true parameters even with a large amount of data. Statistical methods for estimating production functions in these circumstances call generally for some measure of the omitted variables – pests or weather in the above examples. An alternative is to estimate the cost function or factor demands, because these forms do not have the same problem.

Prediction and Extrapolation

In agricultural work, the major reasons to estimate a production function are to predict yields in new circumstances or to assess the efficacy of changing the input mix. Standard statistical methods would seem to suffice for assessing the effect of a small change in inputs. Typically, investigators try many functional forms and different sets of variables before deciding which combination is 'right.' As a result, the statistics calculated for a single regression tend to give confidence intervals smaller than the true intervals, because they do not reflect all prior analyses that were rejected. Partly for this reason, predictions from estimated equations tend to be worse than the regression statistics suggest.

Estimation of Cost Functions

In managed agricultural systems, where least squares yield inconsistent estimates of a production function, the estimation of conditional factor demands or cost functions provides an alternative. This alternative is also used with data aggregated over many crops or many regions. Because input prices can be assumed not to be correlated with an error term reflecting weather or pest conditions, estimating factor demands avoids the problem of the interrelatedness of inputs and the error term.

A system of factor-demand equations is often estimated together. A typical equation for conditional demands is of the form

$$x_i = X_i(w_1, \ldots, w_n, y)$$

In unconditional factor demands, output price p substitutes for output y. Properties of factor demands, described earlier, are imposed as restrictions on the equations.

The Supply Function

To examine the effects of government policies on farm output, economists need to know the relationship among those policies, prices, and farmer behavior – a relationship contained in the supply function. If prices can be considered to be unaffected by the behavior of the farmers whose output is being studied, the supply function can be estimated by least squares. This situation holds if price is not determined with output simultaneously.

Under several circumstances, this assumption is plausible. First, if the supply function is estimated for a small segment of the overall market, such as a small region, farmers can be considered to be price takers. Second, if output price is determined by government policy rather than by market forces, then price truly is determined before output. Third, if it can be assumed that farmers base their planting decisions on the price expected for the crop at the end of the season and if actual price at harvest is related to actual harvest (which is determined by exogenous factors, such as weather and pests), then output is determined before actual price. In this case, price, rather than output, is the dependent variable.

However, if a supply function is estimated for the entire market of an output and if output price and quantity are not set separately, then price is determined by interaction of the supply function with the demand function which reflects consumer desires for the commodity at a range of prices. In this case, information about consumer demand behavior is also necessary to find the supply relationship. Estimation techniques, such as two-stage least squares and instrumental variables, are used to solve this problem.

Response to Weather

Global climate change should have first-order effects on agriculture (Schenkler and Roberts, 2009). Finding the response of agricultural yields to weather is the first step in finding the effects of predicted climate change on agriculture. Because it is only the effect of weather that is of interest, a response function is estimated as a function of many weather variables and the effects of prices and soil (or other place dependent variables) are all absorbed by fixed effects. Hotter weather is neither always bad nor always good, so response to temperature needs to be modeled flexibly. Using the PRISM data for the US, temperature for each place (e.g., 4 km×4 km square) is summarized as the number of hours in the growing season by temperature bin. Examples of temperature bins are the number of hours at 10 °C and up, the number of hours at 12 °C and up, etc. Let X_{itb} be the number of hours that the temperature is in bin b place i at time t. The vector of the X_{itb} is $X_{it}=(X_{it1},\ldots,X_{itn})$ where there are n bins of temperature. A conformable coefficient n-vector is β. Similarly let y_{it} be the yield in place i at time t, δ_i be a dummy variable that is one only in place i, and ω_t be a dummy variable only when the time is t. With an error terms ε_{it}, the equation to be estimated is

$$y_{it} = X_{it}\beta + \delta_i + \omega_t + \varepsilon_{it}$$

This regression captures the response to temperature, accounting for place-related things like soil and time-related things like prices through the dummy variables. The framework can be enlarged by including precipitation, by breaking the variables down by month (e.g., temperature above 10 °C in June), by including richer functional forms (e.g., translog, quadratic, etc.), and by including spatial autocorellation in the error terms.

Use of the Basic Theory of Production

The theory of production and the techniques used to develop quantitative estimates of the theoretical relationships are outlined in the previous description. The ultimate reasons for conducting studies of farm production are to improve farm production (the field of management economics) or to examine the effects of government policies (the field of agricultural policy). The use of the theory and quantitative relationships for examining input levels, farm-level resource allocation, regional modeling of agriculture, and agricultural policy analysis is described in the following section.

Input Intensity

Although it is often safe to assume that farmers use levels of inputs that maximize their profits, at times it is useful to examine effects of alternative levels of input use and production technologies, such as irrigation techniques. The choice of functional form for the production function makes a great difference to recommendations for input use. When a polynomial or Cobb–Douglas form is used, recommended input levels will often be less than when a von Liebig form is used. According to empirical evidence, the von Liebig form is closer to being correct for experimental plots, though nonuniformity in fields leads to arguments for the use of other functional forms.

The choice of irrigation technology involves a trade-off between cost and uniformity. Less expensive techniques can lead to parts of the field receiving more water than necessary and other parts of the field receiving far less water. Because excess water often does not adversely affect crop growth, farmers may 'overirrigate' parts of the field to get sufficient water to the drier parts of the field. Alternatively, farmers can

invest in more expensive technologies that distribute water with great uniformity and reduce water use. A more surprising result is that irrigation equipment can be used to substitute for land! The more expensive technology could be more profitably used by increasing water per acre, which increases yield per acre, and by decreasing the number of acres.

Whole-Farm Models and Planning

Input decisions involve choosing methods to maximize profits for a given crop. In contrast, whole-farm planning involves choosing how many acres to devote to each crop. Depending on the nature of the research question, researchers use several forms of programming techniques to allocate acreage among crops and practices.

Linear programming

The simplest of these techniques is linear programming which is used to analyze static systems with no uncertainty. The linear-programming analysis begins by determining the fixed inputs available to the farm. Fixed inputs are those that cannot be adjusted quickly or easily, such as the total acreage available, soil types, and major capital equipment. The next step is calculating revenues, purchased inputs, and needs for fixed inputs for each crop on a per-acre basis. Finally, total profits (revenues minus costs of variable inputs per acre) are maximized, subject to the constraints on fixed inputs. If fixed inputs are used similarly for each crop, then only the crop with maximum profits per acre will be grown according to the linear-programming algorithm. More generally, the number of crops that will be grown depends on the number of fixed inputs. For instance, if different land types grow a different crop more profitably or if both water and land are in fixed supply, then the programming solution will put acreage into more than one crop.

A simple example is the choice of growing corn and growing sorghum, with profits per acre of π_1 and π_2, respectively. With a total of A acres, A_1 is allocated to corn, and A_2 is allocated to sorghum. The linear-programming problem for crop choice and profit maximization is

$$\max_{A_1,A_2} A_1\pi_1 + A_2\pi_2$$

subject to

$$A_1 + A_2 = A$$

With more complicated production relationships (for instance, with a restricted profit function rather than the simple profit per-acre formulation), nonlinear programming is necessary to solve the problem. In these cases, multiple outputs are more likely than with strictly linear problems.

Quadratic programming

The generalization of the whole-farm planning problem either to a regional model or to a model that accounts for risk involves quadratic programming. Risk is usually incorporated in these models by assuming that a farm operator maximizes profits less a term reflecting the risk aversion of the farmer. In terms of the simple example,

$$\max_{A_1,A_2} A_1\pi_1 + A_2\pi_2 - \lambda Var(A_1\pi_1 + A_2\pi_2)$$

subject to

$$A_1 + A_2 = A$$

where λ is a coefficient reflecting risk aversion and Var refers to variance with

$$\mathrm{Var}(A_1\pi_1 + A_2\pi_2) = A_1^2\mathrm{Var}(\pi_1) + A_2^2\mathrm{Var}(\pi_2) + A_1A_2\mathrm{Cov}(\pi_1,\pi_2)$$

This is a quadratic function in the choice variables A_1 and A_2.

Dynamic programming

Many agricultural problems include dynamic aspects. For instance, because soil loss happens over many years, a model to examine its effects must look a number of years into the future. Similarly, pesticide resistance and fertilizer carryover are multiyear problems. Using dynamic-programming methods, time aspects of these issues are incorporated.

In the dynamic-programming framework, farmers are assumed to care about future as well as current profits. At the same time, it is assumed that current profits are more valuable than future profits because of the existence of alternative investment possibilities and uncertainty about the future. In other words, future profits are discounted relative to present profits. The discounted value of future profits, found by dividing future profits by a discount factor related to the interest rate, is termed the present value of future profits. The dynamic-programming problem involves maximizing the sum of present-value profits over time.

Constraints on the maximization problem, such as the effects of practices on soil erosion and, therefore, on soil quality, involve multiple years. These equations are termed 'equations of motion' because they describe how variables, such as soil quality or pest resistance, change over time.

Controlling pests over 2 years provides an example of dynamic modeling. Let $s(t)$ be pest population at time t, and let j (s) be the year to year increase in pests. With pest control, v, applied at a cost of w per unit, profits with a given pest level are $\pi_1,(p, s)$- vw in year t. With the discount rate, r, the dynamic problem for a 2-year model is

$$\max_v \pi_1(p_1, s_1) - v_1w + \pi_2(p_2, s_2)/(1 + r) - v_2w/(1 + r)$$

subject to

$$s(2) = s(1) + j[s(1) - v_1]$$

Because the function, j, is generally not linear, the problem is not linear in the choice variable, v, and requires nonlinear programming.

When the equation of motion is influenced by a random element, ε, the resulting problem is a stochastic dynamic-programming problem. Because profits are no longer deterministic, expected profits are maximized. In terms of the example,

$$\max_v \mathrm{E}\{\pi_1(p, s) - vw + \pi_2(p, s)/(1 + r)\}$$

subject to

$$s(2) = s(1) + j[s(1) - v_1] + \varepsilon$$

where **E** is the expectations operator. There are computer codes to solve these problems, but computational difficulties increase greatly as the number of equations increases. Thus, the decision to add stochastic and nonlinear elements to a model comes usually only with less thorough modeling of other elements, such as seasonality in labor or number of crops modeled.

Regional Models

Supply functions and demand functions (amount of product purchased by consumers as a function of price) can be combined to give equilibrium (quantity supplied equals quantity demanded) models of agriculture on a regional (or even national) basis. These models are used to analyze the effects of such issues as how government policies affect cropping patterns, the optimality of water use rules, and the costs of soil preservation. In California, water is allocated to districts based on political and historical factors. Regional production models are used to determine how much more money could be made in the farm sector if water were allocated to maximize profits. In Iowa, a soil preservation law requires great care in farming very erodible land. A regional model was used to determine the cost of existing regulation and compare it to more and less restrictive regulations. Linear and quadratic-programming methods are used generally to analyze these types of models.

Implications for Agricultural Policy

Policy issues are often centered on farmer response to government-imposed price policies. The aggregate supply curve for a crop can be used to analyze the effects of price changes on production. For instance, if the government lowers the support price for a crop, the supply curve would indicate by how much production would decrease. To determine who gains and who loses from agricultural policy, both aggregate supply and aggregate demand curves are necessary to determine the effects on consumers. In the above case, a drop in price would hurt producers, but consumers would benefit from lower prices.

A more complicated example is the probable effects of a mandate for the use of ethanol or other biofuel. Such a mandate would increase corn output (requiring an estimate of the supply curve for corn). It would also produce byproducts that compete with soybeans, lowering soybean demand. The supply curve for soybeans is also needed to determine the effects on the soybean market. Complicated analyses of this nature are underlain always by the estimated supply relationships of the crops.

Issues in Economics

It is assumed that agriculture is a relatively static industry in the proceeding analysis. In other words, farmers operate in basically the same way year after year and change their behavior only in response to input and output prices. Of course, this assumption is wrong. Farming has changed substantially over time, in response to changes in technology, regulations, and altered market circumstances. These changes are reflected in contemporary work in production economics.

Technological Change

Supply curves change over time because of technical change. Technical change involves increases in output above that which can be accounted for solely by changes in input use. Examples include improvements in varieties, invention of the tomato harvester, and better pest management. The challenge is to measure the increases in output (or savings in inputs) caused by new technologies. Three approaches are used: experimental plots, time trends, and proxy variables.

For a discrete event, such as hybrid corn, experimental plots are planted with the old and new varieties. If the new variety has desirable characteristics, such as greater output, pest or drought resistance, etc., then it is a possible improvement. To be a technical change (and a real improvement), it must also increase profits (or decrease risk).

The time-trend approach involves estimating a production function with a trend term, for instance

$$y = e^{rt} f(x_1, x_2)$$

where t is time and r is the rate of technical change. In this case, the cause of the change is not specified.

The last approach is to use proxies, such as agricultural experiment station expenditures, for new techniques. An example of such a functional form would be

$$y = I^{a} f(x_1, x_2)$$

where I is the expenditure on research and development. Estimates of productivity that account for research and development show that the returns to research activities are quite high.

Technical progress causes major problems for agricultural price-support activities because it increases output. Price-support authorities find it necessary to purchase ever larger quantities of product, or to restrict output, to continue to support prices.

Farm Size

Returns to scale have real consequences for farm demographics. Middle-sized farms in the US are decreasing in number, whereas larger and smaller farms both seem to be increasing. One of the driving economic forces in this revolution (at least for wheat) is returns to scale. If a farm is operating with increasing returns to scale, it can increase its output more quickly than its costs increase; the farm will expand. If a farm is operating with decreasing returns, it will benefit by reducing its size. The range of output where the farm faces constant returns to scale yields the minimum cost per unit of production and is termed the minimum efficient scale. Many crops, such as wheat, are grown in vast expanses to take advantage of large equipment. The large equipment is less costly per acre if the farm has enough acres to average out the capital costs.

Overproduction Trap

Supply curves may not be the same for a price increase and a price decrease because factors of production can easily move into agriculture but not out. Capital (such as tractors), for which farmers paid large sums, cannot be resold at the same price.

For example, the Russian Wheat Deal led to greatly increased wheat prices and the expectation that high prices would continue. In response, farmers purchased considerable quantities of equipment to expand output. When wheat prices subsided, the additional investments could not be converted into other uses and remained in the hands of farmers. The farmers continued to produce high output because they already owned the equipment and had already prepared the land.

This phenomenon is called the overproduction trap. Production economics is used to estimate how fast production will respond to increased prices and to make a separate estimate of how fast production will respond to lowered prices.

Glossary

Agricultural extension The application of scientific research and new knowledge to agricultural practices through farmer education.

Biofuels Fuels produced from renewable biological resources, such as plant biomass and treated municipal, and industrial waste.

Collective action Voluntary action taken by a group with common interests. In agriculture this can include the formation of producer groups, farmers' associations, or cooperatives in order to increase economies of scale, for cost effectiveness or to better access services or markets.

Commercialization The process by which a new product or service is introduced into the general market. In smallholder agriculture, this often refers to moving from subsistence production to market-oriented production.

Consultative Group of International Agricultural Research (CGIAR) A global partnership that unites organizations engaged in research for a food secure future. Research is carried out by the 15 centers who are members of the CGIAR Consortium in close collaboration with partner organizations.

Eco-certification Where an independent agency, such as a government, nongovernmental organization, or an industry consortium tests or verifies that a certain more sustainable practice has been followed in the production of goods or services.

Latex The colorless or milky sap of certain plants, such as rubber trees, that coagulates on exposure to air.

Medicinal species Plants whose components, such as bark, roots, or leaves, are used as natural medicines.

Payments for ecosystem services (PES) An umbrella term for a variety of schemes, in which the beneficiaries or users of ecosystem services provide payment to the stewards or providers of ecosystem services.

Silviculture The branch of forestry dealing with the development and care of forests.

Background

In agricultural research for development, partnerships are commonly formed to achieve specific outcomes through combining the strengths of different organizations. As in many areas of crop research and development, the breadth of the field of agroforestry is beyond the capacity of a single institution to manage. Partners bring different skills and experience, such as research to generate knowledge and innovation, local knowledge and expertise, upscaling to translate knowledge into action, capacity development and education, policy and institutional reform, and finance.

Partnerships are established between organizations that include research institutions, agricultural organizations, donors, private sector organizations, and government and nongovernment agencies. In agroforestry, which often sits somewhere between the mandates of agriculture and forestry institutions, partnerships cross the boundaries of agriculture, forestry, environment, conservation, and climate change.

Partnerships between public and private sector organizations in agricultural research and development are viewed as having the potential to reduce the cost of research, facilitate innovation, and enhance the impact of research on smallholder farmers and other marginalized groups in developing countries (Spielman *et al.*, 2007). Such partnerships may also be able to increase the level of private sector investment in poorly performing agricultural value chains (Poulton and Macartney, 2012).

Public–private partnerships (PPPs) can broadly be defined as collaborations between public sector and private entities who share costs, risks, and benefits in order to jointly plan and implement activities toward shared objectives (Spielman *et al.*, 2010). The aim of these collaborative initiatives is to overcome constraints, such as market failure, institutional constraints, and systemic weaknesses, in order to produce agricultural knowledge and technology (Spielman *et al.*, 2007).

Spielman *et al.* (2007) have emphasized the importance in partnerships of clearly defining a problem, its solution, and the resources required, and of having effective monitoring, decision-making and communication mechanisms in place. These factors are crucial to achieving trust between public and private partners (Poulton and Macartney, 2012) and in coordinating knowledge amongst multiple actors (Spielman *et al.*, 2007).

On the basis of PPPs among Centers of the Consultative Group of International Agricultural Research (CGIAR), Spielman *et al.* (2007) classified five types of PPPs according to the role of partners in contributing finance, carrying out research and development, deploying products, monitoring, evaluating, and planning.

1. Resourcing: private partner contributes funding or expertise.
2. Contracting: private partner contracts CGIAR facilities or expertise.
3. Commercialization: private partner commercializes, markets, and distributes CGIAR research findings.
4. Frontier research: private partner conducts research jointly with the CGIAR.
5. Sectoral/supply-chain development: private partner contributes within a partner network to supply chain development.

Almost half of the PPPs in the CGIAR aim to convert research results into products for the poor. Approximately 30%

 doi:10.1016/B978-0-444-52512-3.00026-7

of the PPPs reviewed in the study are geared toward sector or supply chain development (Spielman *et al.*, 2007). Within this type of PPP are activities aimed at strengthening collective action, developing technologies, building market linkage, and infrastructure (Spielman *et al.*, 2007).

The case studies analyzed in this article – three out five of which involved a CGIAR Center – tended to be a combination of Spielman's categories with most involving resources from the private sector, joint research, and some aspect of supply chain development among private and public partners. All were strongly geared toward poverty alleviation among smallholder farmers and several incorporated strong elements of improved environmental management.

Public–Private Partnerships in Agroforestry

The involvement of PPPs in agroforestry is a relatively new phenomenon in which private companies wishing to increase their market supply of a product, develop 'new' commodities to meet market demand, and improve the functioning of supply chains formally collaborate with public partners, such as international and national research organizations. Typically, the objectives of these collaborative arrangements are to protect the natural resource base of a commercially important tree species and to develop improved tree crop varieties with increased quality or productivity. In addition, such partnerships embrace government ministries engaged in the important role of formulating and enabling policies as well as nongovernmental organizations (NGOs) working with farmers and product processors.

PPPs in agroforestry involve partners in a number of different roles and approaches. What determines the effectiveness of successful partnerships, the achievement of partnership goals, and the challenges and future opportunities for PPPs in agroforestry commodities are examined here. The focus is on agroforestry products that currently command a private value – via income generation, subsistence value, or reduction of production shocks (Gruère *et al.*, 2006) – or those that have potential to generate income from market transactions in the future. The hope is that the lessons learned from current PPPs in agroforestry can be integrated into future partnerships that focus on intermediary and underdeveloped agroforestry commodities that have the potential for livelihood and environmental gains.

This article examines well-established agroforestry products and their market potential as well as the factors specific to agroforestry supply chains, and their development for products considered intermediary and underdeveloped. Consideration is also given to the complementary role of agroforestry in natural resource management. Six case studies of agroforestry PPPs from a range of countries are included to provide examples of how different public and private sector stakeholders are contributing resources, expertise, skills, and financial investment to enhance market supply of agroforestry products and improve environmental sustainability.

The role of PPPs in payments for ecosystem service (PES) schemes is also discussed as a form of PPP that involves public and private sector actors as providers and buyers of services that include carbon sequestration, watershed protection, and biodiversity protection, many of which can be provided by agroforestry systems.

PPPs are also emerging in tertiary agricultural education with the aim of overcoming a variety of constraints. An overview of these partnerships and their benefits to businesses and universities is given in relation to their ability to stimulate joint research, innovation, greater funding, and improved dissemination of knowledge in agroforestry and other fields of agriculture.

Smallholder Farmers and Agroforestry

An estimated 2.5 billion people around the world are involved in full- or part-time smallholder agriculture (FAO, 2008). Asia and Africa have the highest proportion of small farms, with farm size ranging from 1 to 1.3 ha (IFAD, 2013). Although smallholders contribute significantly to poverty reduction and food security through cultivating field and tree crops as well as livestock, fish, and other aquatic organisms, they also comprise the majority of the world's undernourished population and most of those living in absolute poverty (IFAD, 2011). Of the 1.4 billion people living in extreme poverty (on less than US$1.25 a day) 75% live in rural areas of developing countries, especially subsaharan Africa and southern Asia where agriculture is their main source of livelihood (IFAD, 2011). There are an estimated 870 million people considered food insecure and even more suffering from 'hidden hunger' caused by micronutrient or protein deficiencies (FAO, 2013).

There are strong links between improvements to smallholder agriculture and poverty reduction. Irz *et al.* (2001) estimated that for every 10% increase in farm yields, there was a 7% reduction in poverty in Africa and more than a 5% reduction in Asia. The introduction of new crops and the promotion of underexploited traditional food crops among smallholder farmers have the potential to improve nutrition through providing a variety of foods and in sufficient quantities (Negin *et al.*, 2009).

Smallholder farmers grow 70% of the world's food, in cocoa as much as 90% (Fairtrade Foundation, 2013), yet they receive only a small percentage of the final retail price, just 7–10% of the supermarket retail price for coffee growers and less than 3% of the retail price for smallholder tea producers.

Commercialization of smallholder production (i.e., moving from subsistence-based production to market-oriented production) has been shown to result in welfare gains and poverty alleviation through gains from specialization and comparative advantage, larger-scale production and regular interaction, and exchange of ideas and technological change (Barrett, 2008).

One of the main issues with the commercialization of agroforestry products is the time lag between planting and harvesting (Ajayi *et al.*, 2007), which can be 10 years or more in some cases, although this can be reduced on occasions when alternative propagation methods are adopted, such as vegetative methods, for the propagation and early production of fruit trees (Leakey, 2004). Keeping farmers and others along the supply chain (as well as investors where private or public funding is involved) motivated during this period is a significant

challenge. A lack of business skills and ability to link agroforestry products with markets can be another constraint.

The increased complexity of agricultural markets means that the actors along market chains must collaborate in order to successfully harness business opportunities (Humphrey and Memedovic, 2006). Interventions aimed at developing supply chains look beyond individual actors, such as input suppliers, producers, processors, or traders in order to increase the benefits to smallholders from participating in markets (Donovan *et al.*, 2013).

PPPs are one key element to facilitate smallholders benefiting from market opportunities (World Bank, 2007). Interest in PPPs has increased in recent years because of the potential of such partnerships to improve the functioning of supply chains (Poulton and Macartney, 2012).

Agroforestry, Supply Chains, and Markets

Agroforestry, Its Products, and Services

Agroforestry – the integration of trees in agricultural landscapes– is a traditional land use practiced by farmers throughout most of the world. Zomer *et al.* (2009) found that 48% of the world's farmland has greater than 10% tree cover which represents more than 1 billion hectares of land and 558 million people. Six million square kilometers – or 27% of agricultural land globally – has more than 20% tree cover. Agroforestry systems range from home gardens to subsistence livestock and pastoral systems, staple crops, on-farm timber production, tree crops of all types integrated with other crops, and biomass plantations.

Agroforestry commodities can be clustered according to their use (**Table 1** for the main product groups), including:

- Trees that produce edible fruit, nuts, or oil for human food, such as *Allanblackia* sp, *Theobroma cacao*, and *Dacryodes edulis*.
- Timber and fuelwood trees for shelter and energy, such as *Acacia* and eucalyptus.
- Fodder trees that improve smallholder livestock production, such as *Calliandra calothyrsus*.
- Medicinal trees, such as neem (*Azadirachta indica*), clove, cinnamon, and *Warburgia ugandensis*.
- Trees that produce gums, resins, or latex products, such as rubber (*Hevea brasiliensis*).
- Biofuels, such as *Jatropha curcus*.

Many trees and agroforestry systems are multipurpose and in addition to providing commodities have been shown to deliver ecosystem services and environmental benefits,

Table 1 Suggested classification of agroforestry products and markets

Product	*Intensity of production*[a]	*Scale of an individual enterprise*	*Current demand*[b]	*Market actors*	*Market geography*[c]	*Potential future market value*[d]	*Potential sustainability threats*[e]
Liquid biofuels		Large scale	+	Formal	L-R-I	?	
Solid biofuels	−	Small scale	+	Informal	L-R	−/+	
Charcoal	−	Small scale	++	Informal	L-R	+	Deforestation
Timber	+/−	Large and small scale	++	Informal-formal	L-R-I	+	Deforestation
Fodder	−/+	Small and large scale	+	Informal	L	+/−	
Indigenous fruit	−	Small scale	+	Informal	L-R	−/+	Unsustainable harvesting
Exotic fruit	−/+	Small and large scale	++	Informal-formal	L-R-I	+	Intensity of external input use
Medicinal species	−	Small scale (Africa) and large scale (China)	+	Informal	L	−/+	Unsustainable harvesting
Industrial products (oils and resins)	−/+	Small to large scale	+	Formal	I	?	Unsustainable harvesting
Seeds, seedlings, and other planting material		Generally small scale	+	Informal	L	?	Poor quality material resulting in poor quality trees and products

[a]Low level of on-farm production, i.e., mostly extractive resource use from the existing on-farm, communal area, or forest resource base, + on-farm production.
[b]++ High.
[c]L, Local; R, Regional; I, International.
[d]Growth potential + high −/+ medium.
[e]The drivers behind sustainability threads may be complex, for example, population growth and land and tree tenure systems may drive unsustainable harvesting practices and deforestation.

including biodiversity conservation, soil enrichment, erosion control, and air and water quality (Jose, 2009). Select agroforestry species can also provide nitrogen fixation (Sileshi *et al.*, 2008) and shelter for livestock and crops; increasing production. Tree-based production systems may also support biological, economic, and social resilience under anthropogenic climate change (Thorlakson and Neufeldt, 2012).

Agroforestry supports food and nutritional security through the direct provision of food, raising farmers' incomes to buy food, providing fuel for cooking to make food suitable for consumption and through various ecosystem services that support food production, such as pollination (Jamnadass *et al.*, 2013). Agroforestry also provides dietary diversity and variety in food flavors. In addition, agroforestry products have value in cosmetic and pharmaceutical industries.

Although it is estimated that forests and trees outside forests contribute in some way to the livelihoods of more than 1.6 billion people globally (World Bank, 2008), the varying levels of dependence of different communities on tree products and services and how this changes over time is often not well described or adequately acknowledged in rural development practice (Byron and Arnold, 1997). This reflects the ubiquity of tree products and services and the complex interconnecting pathways by which trees impact livelihoods.

Agroforestry Supply Chains and Their Development

The global export market value of agroforestry commodities is estimated to be in the tens of billions of US$ per annum (Place *et al.*, 2011; Dawson *et al.*, 2013). Yet agroforestry is still often viewed more as a natural resource management activity than a commercial enterprise (Russell and Franzel, 2004).

Tree products are observed to play a vital role in rural livelihoods in the tropics – used in almost every community for construction, fencing, furniture, foods, medicines, fibers, fuels, and fodder – yet quantifying their value and that of the environmental services provided by trees is complex. The many and varied sources of tree products and services (both inside and outside forests) are characterized in different ways by national governments' departments of forestry and agriculture (de Foresta *et al.*, 2013).

Some tree products enter local, national, and international markets, whereas others (although not widely sold) meet basic human needs and are of particular cultural significance (Place *et al.*, 2011). Tree products, such as timber have an investment role for smallholder producers, whereas edible fruit in addition to serving as cash crop has a nutritional security function (Jamnadass *et al.*, 2011).

Informal trade in unmonitored local markets, direct household provisioning, and the exclusion of wild-harvested resources from most large-scale household surveys (Shackleton *et al.*, 2007, 2011; Angelsen *et al.*, 2011), are all reasons why the FAO (2010) figures of US$19 billion for nonwood forest products from forests is unable to adequately represent actual value.

The supply chains for tree products and services generated under agroforestry systems vary considerably in their level of development. A significant focus for PPPs in agroforestry is the further development of these supply chains, from tree domestication for higher quality, greater uniformity and increasing production to better techniques for harvesting and storage, improving processing, and ensuring available markets.

The general components of the agroforestry supply chain are similar to those found in the supply chains of other agricultural products (**Figure 1**). This generic structure has been developed further to illustrate specific agroforestry supply chains (Facheux *et al.*, 2006; Holding Anyonge *et al.*, 2011).

Many agroforestry tree species are wild or semidomesticated (defined by Gruere *et al.* (2008) as underutilized) although they are of high value to local communities, such as the fruit of the baobab tree (*Adansonia* sp.). Some species have been the subject of two decades of intensive domestication (Leakey *et al.*, 2012) and are widely marketed. Underutilized species are generally in abundance locally rather than globally and have high levels of local rather than scientific knowledge and limited current relative to potential value (Gruere *et al.*, 2008). There is emerging interest in species, such as baobab, *Allanblackia*, and tamarind, all of which have European Commission approval for human consumption, and there is high potential for domestication of a range of tree species for on-farm production through the development of cultivars based on market needs.

There has been considerable research generated by both public and private sectors on well-established agroforestry products, such as coffee, palm oil, citrus, and conventional fruits such as apples and olives, which are in production across the world (Jamnadass *et al.*, 2011). However, there is evidence of substantial neglect in some cases, relative to the importance and potential of some products, i.e., horticultural crops (Weinberger and Lumpkin, 2007).

Those products considered intermediary, such as some natural gums and certain indigenous fruits, may be highly commercialized commodities with national as well as regional trade, for example, kola nuts in West and Central Africa (Facheux *et al.*, 2006). Others, such as safou and marula, are highly valued and traded at the local level and have traditional and cultural importance. There are five main aspects which set agroforestry products apart from those of other agricultural crops, some of which are already the focus of PPPs.

1. For agroforestry products, markets for seed and seedling supply may be weak or missing (Lillesø *et al.*, 2011).
2. Information on plant production and plant management may be constrained.
3. Owing to their perennial nature, tree crops experience a longer time lag between planting and harvesting as compared with annual crops. However, their production may be more resilient to seasonal weather variations that can reduce the production of annual staples, and they are more likely to be produced in mixed farming systems that support some resilience in production.
4. In many countries, agroforestry as a subsector is located somewhere between the responsibilities of the Ministry of Agriculture (MoA) and the Ministry of Forestry and may therefore 'fall through the cracks' in the provision of suitable support (Temu *et al.*, 2010).
5. Trees have dual functions in providing important wider environmental services at the same time as the production of fruit, timber, medicines, and other products (Leakey,

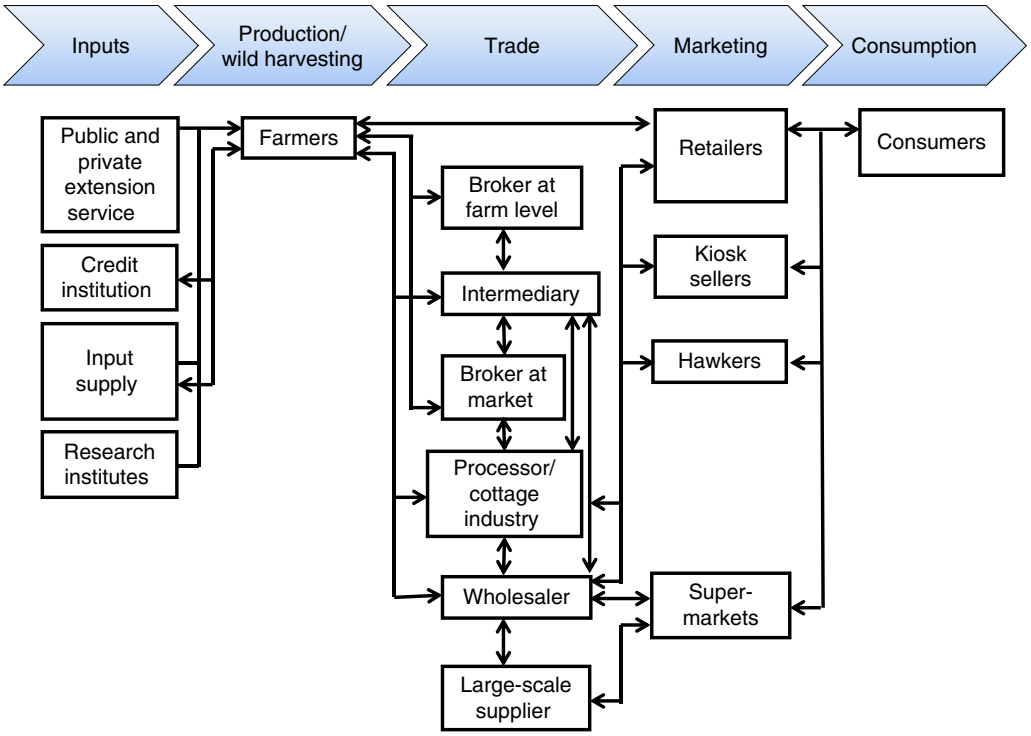

Figure 1 Generic agroforestry supply chain (arrows show product, information, service, and financial flows).

2001). The opportunity to support environmental service provision and production gives added value that can be exploited through PPPs.

The first two aspects are constraints potentially shared with other underdeveloped/underutilized crops and limit supply and its ability to respond to expanding demand. Aspects (3) and (4) are particular to the core characteristics of tree products.

With regard to policy constraints, Place *et al.* (2012) outline three key policy areas that can contribute to agroforestry benefits being more widely distributed: land and tree tenure, equitable supply systems for seeds and seedlings, and increased investment in agroforestry.

Gruère *et al.* (2006) identified the necessary conditions for achieving successful commercialization of underutilized plant species over time, namely: expansion of demand, improved efficiency of production, marketing channels, and supply control mechanisms (Gruère *et al.*, 2006, p. 25). Aspects (1)–(3) can be summarized under Gruere *et al.*'s 'improved efficiency of production and marketing channels.' The process of meeting conditions for successful commercialization of underutilized crops and the position of selected agroforestry products within this process are highlighted in Figure 2.

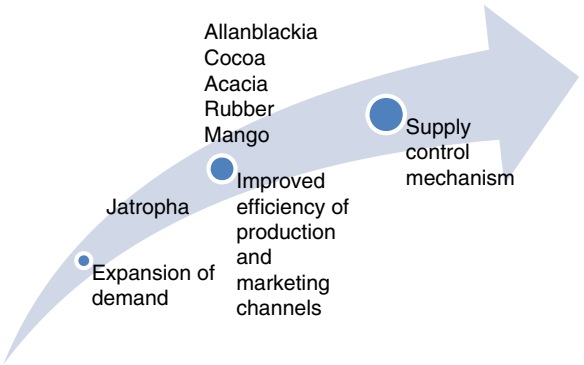

Figure 2 Process of commercializing underutilized crops. Adapted from Gruère, G., Giuliani, A., Smale, M., 2006. Marketing underutilized plant species for the benefit of the poor: A conceptual framework. Environment and Production Technology Division (EPT) Discussion Paper 154. Washington, DC: International Food Policy Research Institute (IFPRI).

Case Studies

The following six case studies illustrate how different PPPs have emerged in agroforestry to meet specific challenges, primarily: research to improve product quality and supply, the further development of supply chains, enhancing farmer participation in markets, and improved environmental management. The products on which they are focused vary from well-known crop (*Acacia*, cocoa, mango, and rubber) to underdeveloped (*Allanblackia* and *Jatropha*) ones.

The common goal among the partnerships profiled is the alleviation of poverty through increasing the commercial viability of agroforestry products. For this reason, the case studies are presented according to their perceived level of impact in terms of improving farmer livelihoods and increasing the value of agroforestry products.

The scale at which the partnerships are operating vary from local (mango, rubber, and *Jatropha*) to regional (cocoa), national (*Acacia*), and multinational (*Allanblackia*).

The level of current and potential future success varies among the PPPs in the case studies as does their long-term sustainability. Although *Acacia* growing in Vietnam is currently highly successful, there are potential risks from pests and diseases. The partnership for cocoa in Côte d'Ivoire is working well at the regional level but there is substantial investment required to scale up efforts. For rubber in Indonesia and mango in Kenya, local-level impact has been achieved but the partnerships have not been extended further. For the allanblackia partnership to achieve the desired impact, considerable work is required in the area of domestication of the species.

Public partners involved in the six case studies include government agencies, international and national research organizations, development organizations, national and international NGOs, donors, certification bodies, universities, and other tertiary education institutions. Private sector partners include multinational companies, public–private enterprises, processing companies, producer associations, and in some instances farmers themselves.

The way in which each of the partnerships is managed varies from informal agreements (*Acacia* and *Jatropha*) to cofinancing arrangements (mango) and contractual agreements overseen by steering and technical committees (cocoa, *Allanblackia*, and to some extent rubber).

Acacia mangium and *Acacia auriculiformis*

There are more than 1300 species of *Acacia* throughout the world with more than 900 of these found in Australia. Many *Acacia* species are valuable for their timber, which is used for fuelwood, sawn timber, and pulpwood for the paper industry, whereas some species also yield tannins and gums. *Acacia* trees are leguminous and many are able to fix nitrogen in the soil. They tend to tolerate soils with low fertility.

Background

In 1943, Vietnam had 14.3 million hectares of forest (Braidotti, 2012). By 1995 approximately 42% of this had been destroyed, largely due to overharvesting and conversion to agriculture during decades of war and severe poverty (Braidotti, 2012). The use of the herbicide Agent Orange in southern Vietnam during the war years of the 1960s and 1970s compounded the situation.

As part of their landholdings, many smallholder farmers in Vietnam have some land that is not arable, such as hilly slopes with shallow, rocky, and degraded soils. These marginal conditions severely limit the income they can gain from agricultural crops.

In the 1980s, due to a shortage of timber supply and as part of a major reforestation program, the Forest Science Institute of Vietnam (FSIV) began to investigate fast-growing tree species that could be grown in short rotations on degraded soils.

The partnership

Partnerships were formed – involving the following – to progress the development of an industry in short rotation *Acacia* plantations:

- FSIV – breeding programs, training, and extension.
- Australian Center for International Agricultural Research (ACIAR) and Australia's Commonwealth Scientific and Industrial Research Organization – expertise on commercial tree growing in developing countries.
- Swedish international development agencies – financial and technical support.
- Provincial and local forest development companies (usually a combination of public and private interests).
- Smallholder farmers.

The type of partnerships established between forest development companies and smallholder farmers range from formal contracts under which companies provide seedlings, fertilizer, technical advice, and other inputs, and farmers provide land and labor with an agreed sharing of returns, to less formal agreements.

In trials of possible species, two Australian *Acacias* proved especially suitable: *A. mangium* and *A. auriculiformis*. Clonal plantations of the interspecific hybrid *A. mangium* × *auriculiformis*, developed through FSIV's own research program are now the most widely planted *Acacia* variety (Dinh Kha *et al.*, 2012) after *A. mangium* and grown from the north to south of the country, including in the Mekong Delta.

Acacia trees are generally grown in Vietnam in small woodlot plantations on short rotation, although intercropping in early years of the rotation does occur with crops such as cassava, and some farmers grow *Acacias* at wider spacing over crops, such as tea, or in rotation with other crops. *Acacia* trees are easy to cultivate and grow quickly.

Plantations can be harvested to yield small logs after 5–7 years (Braidotti, 2012), depending on site quality, providing farmers and companies with early returns. Logs of larger diameter can continue to be grown on longer rotations, earning higher returns after a few more years.

Acacia timber provides excellent fiber for pulp and is good for furniture manufacture; a major industry in Vietnam. The productive *Acacia* plantations support many processing factories across the country. Farmers sell their trees either to company buyers, independent wood contractors (who function as 'middle men'), directly to pulpmills, woodchip mills, sawmills, or veneer mills.

To improve plantation productivity, the FSIV established breeding programs to produce genetically improved *Acacia* planting stock for growers. They also developed technical systems and associated training for nurseries. Clonal nurseries producing elite acacia hybrid clones certified by Vietnam's MoA and Rural Development are either by government- or privately run and some farmers also grow *A. mangium* seedlings for sale in small roadside nurseries.

Extension packages recommending simple establishment and plantation management procedures have also been developed and promoted through the national forest extension service and widely adopted.

Other research has focused on silvicultural methods that protect site resources and support sustainable production over successive rotations. The importance of retaining harvesting residues on site and minimizing soil disturbance by avoiding burning and repeated cultivation has been demonstrated but not yet widely adopted. Thinning and pruning techniques to

increase the production of larger diameter sawlogs have been researched but likewise are not yet widely adopted.

ACIAR-supported projects have helped to build technical capacity in Vietnam and developed advanced *Acacia* breeding programs. Breeding populations and seed orchards have been established to produce improved varieties of the parent species and for hybrid breeding.

Successes

Acacia trees now cover approximately 3% of Vietnam's land surface: 600 000 ha of *A. mangium*, 90 000 ha of *A. auriculiformis* and 400 000 ha of clonal plantations of *Acacia* hybrid (*A. mangium* × *auriculiformis*) (Harwood and Midgley, 2012). About half of these are cultivated by smallholder farmers on less than 10–20 ha. The remainder are owned and managed by forest companies and state enterprises.

The timber processing industry has shifted from state-owned enterprises to private companies through Vietnam's economic liberalization policies. By 2008, the timber-processing sector had expanded into a US$3 billion industry (Putzel *et al.*, 2012), one of Vietnam's top five export sectors and a major source of demand for logs and sawnwood.

In 2011, *Acacia* trees provided approximately 90% of Vietnam's woodchip exports of more than 5 million bone dry metric tonnes (Harwood and Midgley, 2012). In addition, the *Acacia* timber that supplies local pulp mills, sawmills, and downstream wood processors make a significant contribution to rural employment.

The development of a country-wide industry in short rotation *Acacia* plantations has been successful in Vietnam largely because of many reliable commercial markets for the wood that pay a good price for small logs, within easy transport distance of the plantations. Widespread smallholder adoption has also been attributed to the availability of suitable land for planting, land reforms conferring unambiguous ownership of trees, the wide availability of appropriate germplasm for planting, and simple farm establishment requirements (Fisher and Gordon, 2007; Griffin *et al.*, 2011).

Acacia trees help to prevent soil erosion through the development of a heavy litter layer and strongly fix atmospheric nitrogen, thereby improving soil fertility for the next crop. Food crops or other cash crops, such as rubber, can be grown after a rotation of acacias.

Challenges

Although famers and companies have made good profits with *Acacia* growing in Vietnam, the local price of woodchips has only marginally increased in recent years, whereas the Vietnamese Dong has depreciated against other currencies. Relying primarily on exporting woodchips is a risky strategy because of varying commodity prices.

As both furniture manufacturers and pulpwood markets demand the same species, competition exists between these manufacturing sectors, which is good for growers but can create an incentive for premature timber harvesting (Putzel *et al.*, 2012). If smallholders are able to produce higher quality or certified timber, they can often receive greater benefits. There is currently a lack of domestic supply of certified timber which results in Vietnam's furniture companies importing raw materials.

On better soils in Southern and Central Vietnam, rubber plantations can provide more attractive return on investment and timber plantations will increasingly need to be established on less productive land.

Although pests and disease have had little negative impact on wood production of *Acacia* plantations in Vietnam during a 20-year period of widespread planting, they remain a real threat. *Acacia* plantations in Sumatra, Indonesia have been seriously impacted by diseases, in particular Ganoderma and Ceratocystis (Tarigan *et al.*, 2011). Illustrated manuals in both English and Vietnamese language for pest and disease identification have been developed (Thu *et al.*, 2010) and disease surveillance networks are being built. Pathologists with the Vietnamese Academy of Forest Science (VAFS) are screening acacia breeding populations to identify disease-resistant genotypes, and Vietnam has the capacity to rapidly mass-produce resistant varieties. VAFS is also researching and developing other tree genera for plantation forestry, including *Eucalyptus*, *Manglietia*, *Melaleuca*, and *Pinus*.

Concerns have been raised about the environmental impacts of the rapid expansion of large-scale plantations in Vietnam. However, if slow-growing species had initially been chosen for the deforested hillsides of Vietnam, the poverty alleviation benefits would not have been as great as those that have been achieved with fast-growing *Acacias*. If the country now decides to move toward slower-growing species for its plantations, more land under plantations would be needed to produce the same amount of wood that acacias deliver.

Vietnam requires large volumes of timber to supply its US $4 billion processing industries, and 75% of this is imported. The growing of *Acacias* in plantations – half of which are owned and managed by smallholders, with the majority of the remainder under local management – is servicing this industry, providing an alternative to the use of timber from natural forests in Vietnam or timber imported from overseas.

Research focus is increasingly being placed on sustaining productivity within *Acacia* plantations. Highly productive plantations are able to make very efficient use of a small proportion of Vietnam's land base to meet the country's industrial wood requirements, opening up greater opportunities for landscape diversification.

Although distributing improved *Acacia* germplasm to smallholder growers has been highly effective, it is much more difficult to spread improved plantation management practices to tens of thousands of growers. This is an area requiring further research.

Cocoa

The cacao tree, *T. cacao*, is native to southeast Mexico and the Amazon basin. Cacao pods borne on the stems of this small tree typically contain 20–60 beans which are dried, fermented and then used to make cocoa powder, the main ingredient of chocolate. Today, cocoa is mostly produced in West Africa, with more than 30% of the world's supply coming from Côte d'Ivoire. Although cocoa used to be a plantation crop, up to 90% is now grown by smallholders (Fairtrade Foundation,

2011). In Cote d'Ivoire the cocoa industry supports more than 6 million people (Sustainable Cocoa Initiative, 2012) and globally cocoa is grown by 30 million smallholder farmers (Fairtrade Foundation, 2013).

Background

Globally over the past decade, cocoa production has been declining and its quality has varied due to depleted soils, lack of improved planting material, aging trees, pests and diseases, changing weather patterns, and weak rural infrastructure. At the same time, demand for cocoa is increasing and it is estimated that at least 1 million additional tons of cocoa will be needed by 2020 to meet the demand (Fairtrade Foundation, 2011).

Mars Inc., one of the world's largest chocolate producers, launched its sustainability initiative in 2010 with the aim of using only certified cocoa in all of its products by 2020. Research and on-ground projects initiated by Mars toward this goal and increasing the productivity and quality of cocoa are underway in Indonesia, Vietnam, Papua New Guinea, and Côte d'Ivoire.

In Côte d'Ivoire, Mars is focusing its efforts on the country's primary cocoa-producing area of Soubré in the southwest of the country. Land shortages in Côte d'Ivoire limit agricultural expansion, so increasing production requires intensification. Revitalizing the cocoa sector in Côte d'Ivoire necessitates bringing together the private sector, government, and civil society organizations.

The partnership

The Vision for Change program was created in 2010 by Mars in partnership with the Ivorian government, national agricultural institutions and the World Agroforestry Center. The program is strongly geared toward raising farmers out of poverty by helping them to improve their incomes through more productive farms. The goal is to sustainably increase yields for 150 000 farmers in the Soubré region from an average of approximately 400–1500 kg ha^{-1} or more by 2020 through the establishment of 75–100 Cocoa Development Centers, each of which will support up to 20 Village Cocoa Centers.

The major partners in the Vision for Change program and their roles are as follows:

- Mars Inc. – investing in and steering the program.
- World Agroforestry Center – program management, facilitation to coordinate program activities, expertise and resources in cocoa agroforestry, soil management, and tissue culture.
- Center National de Recherches Agronomiques – collaboration on propagating selected high-yielding clones and creating gardens for tree culture.
- Agence Nationale d'Appui au Development Rural – conducting on-farm trials to demonstrate good agricultural practices and rehabilitation of old plots through grafting, and community development activities to benefit farming communities.
- Université de Cocody Department of Statistics – baseline socio economic and cocoa production system survey.
- Université de Bouaké Department of Anthropology and Sociology – baseline socio-cultural survey and cultural analysis.
- National School of Agriculture – strengthening capacity, conducting soil research and training.
- Conseil du Café et Cacao – monitoring, governance, and coinvestment for cocoa community empowerment.

The program also involves other stakeholders and sector investors including the Cocoa Board of Côte d'Ivoire, the World Bank, World Cocoa Foundation, bilateral donors, commercial suppliers, certifiers, and NGOs. The partnership is overseen by a high-level steering committee and a technical secretariat.

The Vision for Change program comprises three concepts: farm-level rehabilitation, community-level empowerment, and sector-level reform. At the farm level this involves the following:

- Providing farmers with quality planting material which relies on research into improved varieties through plant genetics and breeding.
- Rehabilitation of cocoa farms to produce high-yields through using modern, environmentally sustainable agricultural practices.
- Assisting farmers with the skills and tools needed to implement good agricultural practices that can reverse soil nutrient loss and reduce the need to expand cocoa farming into protected forest areas. This includes the effective application of fertilizers, sustainable soil management, pest and disease management, and improved postharvest practices.

Cocoa Development Centers, staffed by agronomists, showcase the best methods for improved and sustainable cocoa production, especially in rehabilitating old cocoa plots with superior planting material. They also provide training to staff of government agencies, local organizations, and private companies who can train farmers in good agricultural practices. Village Cocoa Centers operate as businesses in their own right run by local entrepreneurs. At these centers, local farmers can see best practice in operation, buy superior plant varieties as well as other farm inputs, and receive technical and agronomic advisory services. At the community level, the Vision for Change approach involves community empowerment activities aimed at improving the quality of life in cocoa communities and facilitating better access to public and private development funds.

At the sector level, Mars together with the Cocoa Board of Côte d'Ivoire and MoA work on policy issues and securing ongoing support and investment from public and private sectors. Although the program is currently only operating in Soubré, the partners hope that through effective demonstration of the Vision for Change approach, similar initiatives will operate in other cocoa producing areas of Côte d'Ivoire.

Successes

The success of the Vision for Change partnership depends on an alignment of the problem (i.e., the gap between supply and demand) and agreement on a common goal and vision among all partners. The interventions and activities of the program

support the Ivorian Government's 2QC Program (Program de Qualité, Quantité, Croissance (Quality, Quantity, and Growth Program)) to ensure the sustainability of coffee and cocoa production in the country. Mars is committed to a better supply of cocoa and farmer education because their business depends on the outcome. The effective engagement of national partners has required the private sector to understand the different mandates of government agencies and to invest considerable time and effort in capacity building and advocacy, making use of personnel with the right skills.

Achievements to date under the Vision for Change program include the following:

- The program has already reached 10 000 farmers through the establishment of 16 Cocoa Development Centers and 40 Village Cocoa Centers by 2013.
- Successful propagation of superior germplasm through grafting, embryo culture, and seed gardens; of 11 clones tested from 2010 to 2012, 40% were early maturing and produced 40–60 pods per year 15–18 months after grafting.
- Through rapid appraisal and rapid market appraisals, several indigenous plant species have been identified for diversification on cocoa farms based on farmer's preferences and market potential, including *Milicia excelsa* (Iroko), *Ricinodendron heudelotii* (Akpi), *Spathodea campanulata*, *Beilschmeidia manii*, and *Cola nitida*.
- Funding secured for community empowerment projects, such as the establishment of schools and village water supply systems.

Challenges

Not long after the Vision for Change program was launched in 2010, disputed elections in Côte d'Ivoire triggered a period of intense armed conflict and civil unrest, a great exodus of refugees, and the temporary paralysis of the cocoa industry. Donors and the private sector were initially hesitant to invest amid instability within the country and its government.

There have been ongoing challenges with the partnership, including ensuring timely delivery and technical and financial reporting. Clarifying the need to decentralize the production of planting material to ensure access by farmers and the use of different plant propagation methods to respond to demand were also preliminary challenges.

When the project was first proposed, many farmers believed that Mars and its partners wanted to increase production in order to reduce prices. There was considerable effort invested in communication from Mars, supported by national partners, to convince them that this was not the case. There has also been a need to overcome a mindset of extensive farming and resistance to grafting techniques through the establishment of demonstration sites.

Risk management activities have had to be implemented to address the threat of Cocoa Swollen Shoot Virus Disease. This has involved reviewing the state of knowledge of the disease, organizing training visits to neighboring Ghana and proposing a risk management protocol, and other measures to deliver planting material without spreading disease.

The challenge ahead of the Vision for Change program is to reach 150 000 farmers in Soubré through 1500–2000 Village Cocoa Centers by 2020. To achieve this goal, the program will focus on improved farm inputs that produce measurable income increases, integration of research outcomes into expanded extension services, diversification to ensure sustainable environmental rehabilitation and development of a business model for nursery operators, and the use of additional farm income for improved social services. It is expected to see a transformation of cocoa farming in Côte d'Ivoire from subsistence to entrepreneurial models leading to diversification within value chains and beyond.

Allanblackia

There are nine tree species in the *Allanblackia* genus, all of which are found in the moist forests of West, East, and Central Africa regions extending from Tanzania to Sierra Leone. The *Allanblackia* tree has been used for centuries as a source of edible oil, medicine, and timber. The seeds of the *Allanblackia* tree contain a solid white fat which has traditionally been used for cooking and soap making. It has now been identified as a potentially valuable ingredient for food products and cosmetics. With mature trees able to produce more than 10 kg of oil per year, 3 kg of seed can yield 1 kg of oil (Attipoe *et al.*, 2006).

Background

Around 2000, the multinational consumer goods company, Unilever, analyzed allanblackia oil and found that the oil's composition and structural properties were perfect for products like margarine and confectionary, and decided to explore using allanblackia oil in their supply chain. They began working with subsistence farmers in a number of African countries with the intention of creating a new edible oil crop for Africa grown in agroforestry systems. The strategy now being developed is to use participatory tree domestication to ensure that the farmers are beneficiaries of this initiative.

The partnership

An initial partnership was set up to develop wild harvesting supply chains for *Allanblackia* in Ghana and Tanzania. When it was realized that wild harvesting would not generate sufficient quantities of oil to make it commercially sustainable – only producing a maximum of 200 ton $year^{-1}$ – the initiative sought to create a planting program involving local farmers, focusing on domestication, and growing and planting as many trees as possible, while maintaining existing supply chains.

The Novella Africa partnership was formed in 2002 to work on establishing a sustainable supply of allanblackia oil through domestication techniques, tree management practices, and conservation strategies. The partnership involved more than 30 organizations at the international, national, and local level. Contributions were voluntary at the time, which allowed the project to become established with relatively limited investments. In 2006, a research and development program was established, led by the World Agroforestry Center, to generate the knowledge required to domesticate the species in village nurseries.

Difficulties in managing the project with respect to focus, mass, speed, and accountability led to a restructuring of the

partnership in 2009. A core team was formed, consisting of the following organizations, each of which bring specific expertise to the project and its key goal of proving that *Allanblackia* can be successfully scaled-up at large volumes with attractive prices:

- Unilever – business components, market outlet for *Allanblackia*, investment in product development and establishment of a supply chain.
- Local allanblackia companies: Novel Development Ghana Ltd., Novel Development Tanzania Ltd, and Project Novella Nigeria/Rivers State Sustainable Development Agency – implement local wild harvesting supply chain, link to farmers, and implement components of the domestication activities (planting).
- World Agroforestry Center – development of propagation methods, gene conservation, and integration of *Allanblackia* into agroforestry farming systems.
- World Conservation Union (IUCN) – research into the ecology and abundance of *Allanblackia*, sustainable harvesting, and biodiversity conservation.
- Union for Ethical Biotrade – certification to organic and fair trade standards.
- Form International – designing and implementing planting models.

The collaboration has been formalized via contracts between Unilever and the World Agroforestry Center, the local allanblackia companies and Form International. An independent chairperson heads the team. There is also a technical team that meets and reports regularly, and a web-based tool has been established to share project information.

Each of the partners is contributing to the project in-kind and financially. In addition to this, donors are and have been contributing to the project, including the International Fund for Agricultural Development (IFAD), The Dutch Ministry of External Affairs, Austrian Development Agency, Danish International Development Agency, UK Department for International Development, European Commission, German Federal Ministry for Economic Cooperation and Development (BMZ), Deutsche Gesellschaft für Internationale Zusammenarbeit (GIZ), the Swiss State Secretariat for Economic Affairs (SECO), Swiss Agency for Development and Cooperation (SDC) and Mars Inc.

The team composition and way in which the supply chain for *Allanblackia* operates varies in the three countries. In Tanzania, there is a shift from farmers' groups to a cooperative structure with greater private sector involvement. In Nigeria, the supply chain is government led.

Once collected, the *Allanblackia* seeds are dried and brought to collection centers where they undergo quality certification. The seeds are sent to central oil extraction facilities for extraction under the supervision of the local allanblackia companies. Most of the oil produced is being purchased by Unilever, although the food company Nutriswiss and a cosmetic company have also purchased allanblackia oil.

The World Agroforestry Center is leading the domestication process together with the NGO (Form International) and the local allanblackia companies. Initially, very little was known about the species and the seeds of the tree have proved difficult to germinate, taking more than 7 months. In the wild, a tree needs up to 10–12 years until it starts producing fruit. Although there is still significant work to be done, the first successes of the domestication program have been reported: seed germination has been reduced from 7 months to 90 days and the first generation of *Allanblackia* started fruiting after 6 years from seed.

Domestication efforts will continue to further develop 'superior trees,' through vegetative propagation, that will bear fruit in less than 4–5 years, grow vigorously, and fruit regularly with large fruit. Scientists are working with farmers to capture the most desirable traits from wild trees and reproduce superior types as clonal cultivars.

Experiments are performed on farms, in rural resource centers and specific pilot plots. Rural Resource Centers have been set up to disseminate allanblackia knowledge to farmers managed by national agriculture institutes, community groups, and local NGOs. These serve as diffusion hubs for new technologies, germplasm and knowledge. They have their own tree nurseries, motherblocks (plots with female trees with desirable traits) and demonstration plots, and train farmers in allanblackia propagation and cultivation techniques. The seven Centers also support private satellite nurseries in villages nearby remote farmers (Asaah *et al.*, 2011).

Currently, efforts are focusing on the mass production of seedlings of selected, superior trees, and the development of sound agroforestry systems for large-scale integration of *Allanblackia* with other crop production systems on farms.

Successes

The Novella Africa partnership is very much an African venture, with African research institutes, universities, and NGOs playing a key role. They actively work alongside harvesters, farmers, buyers, oil-seed crushers, and others in the private sector. The involvement of international institutions and significant donor support has been vital to establishing the project.

The commitment of current partners is demonstrated by the time and resources they are investing in the project. The success of the partnership relies on various factors, primarily:

- Transparency.
- Agreement on a common goal leading to common key performance indicators and the development of an agreed work plan.
- Sharing of information, best practices, and areas of key learning.
- Contractual arrangements, which specify the needs to be delivered.
- Monitoring (through a neutral arbitrator) to ensure medium- and long-term goals are met.
- Acknowledgment of successes.

More than 10 000 farmers have planted 200 000 *Allanblackia* seedlings in Tanzania, Ghana, and Nigeria. Functioning local supply chains are in operation in all three countries and there are approximately 250 local buyers that provide a link between harvesters and buyers. Fifteen rural resource centers are providing training and seedlings to farmers.

In terms of domestication, seedlings from 121 mother trees have been established in three genebanks and protocols for vegetative propagation (cuttings, grafting, and marcotting)

developed. Success rates in propagation continue to improve with close to 80% rooting achieved with cuttings and 70% with marcotting. The long seed dormancy period that has frustrated farmers in efforts to produce planting stocks is being reduced with 66% germination being achieved in 90 days.

A monitoring and evaluation program is being implemented which will provide the data needed to assess the future viability of the allanblackia business.

As far as environmental conservation is concerned, IUCN has produced guidelines on best practice for wild harvesting of *Allanblackia* and efforts are being made to ensure that the domestication program enhances biodiversity. For example, the integration of *Allanblackia* into small-scale cocoa farms is being promoted in West Africa to support more biodiverse and resilient agricultural landscapes (Jamnadass *et al.*, 2010).

Challenges

Currently, the potential market demand for allanblackia oil (estimated at more than 30 000 ton year^{-1}) cannot be met by harvesting fruits of wild *Allanblackia*, which yields about 200 ton year^{-1} although this fluctuates (Ofori *et al.*, 2013).

It may be 10–15 years before the first yields of significant size will become available, so keeping farmers interested and enthused is a challenge. Maintaining the wild harvesting supply chain is instrumental as it sets the example of how *Allanblackia* could contribute to increased and diversified income for farmers.

At the start of the project, the main challenge was to realize alignment between partners and for each to understand each other's interests. Individual organizations involved in the partnership are also under pressure from competing priorities and projects they are responsible for in addition to their work on *Allanblackia*.

The Novel Company that was originally established to implement the supply chain in Nigeria dissolved, although its role has now been taken over by the government-run, Rivers State Sustainable Development Agency. Novella Ghana is experiencing problems with supply chains.

As the project progresses through different stages, the partnerships are being reviewed on a regular basis to ensure the right organizations are involved for the right activities. When a partner no longer fits the criteria of the partnership it will be replaced.

In parallel with market-oriented and organizational challenges, the domestication of *Allanblackia* faces a number of constraints, especially in refining appropriate propagation protocols and in devising more efficient methods for delivering superior planting material to growers that is productive and meets farmers' needs. In addition, considerable work is required in understanding how to manage *Allanblackia* trees once they have been introduced into farmland in order that they are productive (Jamnadass *et al.*, 2010).

The project partners believe that several million farmers in Africa could benefit from the trade in *Allanblackia*, which could potentially grow in value to several million US dollars a year and become another significant cash crop in Africa. However, meeting the gap between current demand and supply will require on-going commitment from partners, additional investment in research, and buy-in from national governments and national organizations that can manage the supply chain and make it self-sustainable. In 2016 the project is expected to deliver sufficient data to conclude on the feasibility of upscaling *Allanblackia*.

Mango

The mango tree (genus *Mangifera*) is native to South Asia from where it has been distributed worldwide to become one of the most cultivated fruits in the tropics. It had been introduced to East Africa by the fourteenth century. There are currently more than 350 mango varieties propagated in commercial nurseries and orchards, with many more 'wild' varieties occurring on farms throughout the tropics.

Background

Poor mango production practices in Kenya have led to low-quality produce. Insect pests such as fruit fly and mango weevil, and diseases such as Anthracnose and powdery mildew are major challenges to increased production of quality mangoes. Lack of quality planting material, premature harvesting of fruits, the high cost of harvest losses associated with poor infrastructure, financial constraints, and limited access to markets prohibit smallholder farmers from receiving greater benefits from the mangos they produce. Little is known about the introduced varieties of mango in Kenya and most trees are of unknown seed origin.

The partnership

From 2006 to 2008, a PPP operated that involved cofinancing among the following partners:

- KEVIAN fruit processing company liaised with farmer groups and the out growers for quality control, organized collection of produce, processed fruits, forged links with potential consumers, and promoted local consumption of fruit juices.
- Kenya Gatsby Trust.
- International Center of Insect Physiology and Ecology.
- United Nations Development Program.
- German Technical Cooperation – provided funding for training, equipment, packaging materials, collection centers, and for personnel.
- MoA – trained farmers on the technical aspects of mango production, harvesting, postharvesting, handling, and marketing.
- Kenyan Federation of Agricultural Producers – contributed to organizing farmer groups and associations, trained farmer groups on agribusiness and assisted them in drawing business plans, and networking with stakeholders.

The project was geared toward poverty alleviation of smallholder mango farmers in specific districts in the Eastern, Central, Coastal, and Rift Valley provinces of Kenya through employment creation and local economic development. The aim was to achieve this through promoting mango marketing and value addition/sector development.

The partnership investigated more sustainable use of smallholder mangoes as raw material for cottage industries and for local processing of frozen concentrated mango juice for the domestic, regional, and overseas markets.

Combined, the investment by both public and private partners amounted to approximately €159 000 (US$233 411). These funds were used for activities ranging from training, equipment, packaging materials, collection centers, and personnel.

Successes

The partnership resulted in an improvement in the marketing position of 450 smallholder mango growers which led to an average increase of 42% in their income. Losses at the farm level were decreased by 40% and reduced wastage from farms and at the processing plant decreased by up to 40%. Links were also established between producer groups/associations and the processor.

Challenges

The group approach proved to be a challenge for the partnership, especially with regard to high transaction costs in managing the groups. It was also difficult to ensure quality standards as many smallholder farmers grow different varieties of mangoes leading to limited quality uniformity which negatively affects their income as well as that of the company. It proved to be more beneficial for large-scale farmers to have individual contractual agreements with the processing company but the disadvantage of this approach may be that poverty reduction is more limited. If focus is shifted to large-scale farmers, such as PPP would reach fewer people who in most cases are more resource endowed.

Rubber

The rubber tree (*H. brasiliensis*) is native to the Amazon rainforests of Latin America, but is now grown in many countries around the moist tropics. Latex is extracted from rubber trees using a spout that is inserted into the bark across the latex vessels, just deep enough to tap the vessels without harming the tree's growth. The latex contains approximately 25–40% dry rubber content. There has been a growing trend in recent years away from large-scale plantations to increased smallholder production from plantations, largely due to plantation owners switching to less labor intensive crops.

Indonesia is the second largest rubber producer in the world, supplying approximately 2.3 million tons per year. An estimated 87% of rubber cultivation in Indonesia occurs on smallholder farms averaging 2 ha in size.

Background

The production of rubber in smallholder agroforestry systems (jungle rubber) has been practiced by the communities of Muara Bungo district in Jambi province, Sumatra, Indonesia since 1904 and is the main source of income for smallholder farmers in the district. Rubber-tree gardens are grown in a multistrata system, which forms a secondary forest. Rubber trees are planted alongside other trees that provide local fruits, medicines, and timber for self-use or sale.

Ecologically these jungle rubber agroforests are important; they act as buffer zones for national parks, help maintain local biodiversity, provide watershed protection, and carbon sequestration (Ekadinata *et al.*, 2010). Approximately 60–80% of plant species found in neighboring forests can also be found in the rubber agroforests (Gouyon *et al.*, 1993).

Jungle rubber systems are under threat of extinction because of their low economic viability (Budidarsono *et al.*, 2010) compared with rubber monocultures or oil palm, an industry that is rapidly expanding in the province with plantations dominated by large companies.

Jungle rubber systems produce only about a third of the latex that is produced in intensive monoculture plantations. This is mainly because the trees are generally old and suboptimal planting material is used (Akiefnawati *et al.*, 2010). The quality of the rubber is also lower due to poor harvest and postharvest techniques.

Farmers generally sell their rubber at a low price to local traders, known as 'toke,' who tend to determine the price of rubber subjectively. Farmers can sell their rubber at a higher price to a biweekly rubber auctioneer but this can involve queuing for 2–3 days for the auction and payment. Farmers with higher quality rubber can sell directly to rubber-processing factories for up to 60% more than the cost they would receive from the toke, however, many farmers cannot afford to transport their rubber to a factory.

The partnership

Bridgestone Corporation learnt that the World Agroforestry Center had been working with farmers in Jambi and was keen to support the Center's efforts through its operations in nearby Medan, and to investigate the potential for increased 'dark-green' rubber supply. A Memorandum of understanding was signed by both organizations initially to investigate the potential for ecosystem-friendly (green) natural rubber and later to work together on improving the productivity and quality of jungle rubber.

A partnership was formed with the aim of improving the profitability of jungle rubber (and thus farmers' livelihoods) in the hope that farmers would be more willing to conserve their agroforestry rubber-tree gardens and be less likely to convert them into monoculture rubber or oil palm. The organizations involved and their roles were as follows:

- Bridgestone – funding for economic research and research into productivity.
- World Agroforestry Center – acting as an intermediary providing scientific inputs, sensitizing and connecting farmers with Bridgestone, and documenting outcomes of the work.
- Lembaga Ekolabel Indonesia (Indonesian Ecolabeling Institute) – feasibility study into eco-certification cofinanced by the Rewarding Upland Poor for Environmental Services (RUPES) project funded by the IFAD.
- Konsorsium Komunitas Indonesia – Warung Informasi Konservasi, a NGO – capacity development support in improved rubber harvest and postharvest techniques and environmental aspects of rubber agroforests.
- Waseda University Environmental Research Institute – economic research concerning jungle rubber.

Activities under the partnership were undertaken in the village of Lubuk Beringin, including:

- Investigating the potential for eco-certification of jungle rubber (i.e., whether farmers might be able to receive a

premium price for their rubber in return for maintaining the environmental services of jungle rubber ecosystems).
- Improved techniques for tapping rubber and use of different harvesting tools.
- Introducing a special acid as latex coagulant during postharvest and other techniques to: maintain the full dry content of rubber, produce slabs with regular form, and reduce wastage.
- Rejuvenation of some gardens with superior rubber clone seedlings (type PB 260) that can produce approximately three times more latex (Wibawa *et al.*, 2008).
- Organization of collective transportation to rubber processing factories through the establishment of the Agro Pores farmer's group.

Successes

Improving rubber quality can increase farmers' income from agroforestry, demonstrating that quality improvement could have an impact on conserving rubber agroforestry.

Wulan *et al.* (2006) and Roshetko *et al.* (2007b) have shown that the successful promotion of higher yielding rubber clones (rather than the collection of self-regenerated seedlings) and the better management of plants to reduce input costs and retain some biodiversity in rubber agroforests have led to greater profits for many Indonesian smallholders.

For eco-certification to succeed requires supportive policy. The information gained from the partnership will assist local government to address livelihood, conservation and land use planning issues, and determine what benefits can be gained from well-managed rubber.

Two farmer groups in Lubuk Beringin (Agropores: 15 farmers and Senamat Ulu 10 farmers) have been able to improve their harvest and postharvest techniques, resulting in higher quality rubber and higher quantities. This has given them the option of selling directly to rubber production factories and gaining higher prices.

Some farmers have changed the establishment and maintenance of their rubber gardens, for example, applying chemical herbicide and fertilizers, and fencing their gardens. Some have also used chemicals to catalyze and increase latex production.

The establishment of the farmer-led Agro Pores group has reduced transportation costs enabling farmers to sell direct to rubber-processing factories.

Farmers from Lubuk Beringin are now interacting directly with Bridgestone.

In the neighboring village of Senamat Ulu (not part of the partnership's work), some farmers have begun to implement the new techniques, demonstrating that the information is being transferred to some extent.

Challenges

The risk of farmers converting their agroforestry systems into monoculture into enhance their profitability remains. The achievements under the partnership have so far been limited to the village of Lubuk Beringin and there are no formal agreements that the innovations they have benefited from are a reward for their practices to maintain environmental services.

Different attitudes toward eco-certification exist within different companies, and though some are seriously considering investing in eco-friendly rubber, others are carefully considering that purchasing the product at a premium price may have a distorting effect on the global market.

There is a strong need for raising awareness about the ecological importance of rubber agroforestry and support needed for district and provincial level governments to champion eco-certification or implement any reward scheme that would protect jungle rubber from conversion into other land uses.

Jatropha

Jatropha (*Jatropha curcas*) is indigenous to Central America and produces a seed that can be processed into biodiesel suitable for diesel cars or further processed into jet fuel. The tree is grown extensively in India as well as in the Philippines, Pakistan, and Brazil for its oil.

For many years, farmers across subsaharan Africa have grown *Jatropha* as a fence, hedge, or windbreak. In many parts of Kenya it has been grown as a support for vanilla vines. In recent years, it has been widely promoted as a biofuel crop.

Background

The company, Energy Africa Ltd., was established as a social business in Kenya in 2006 with the aim of working with farmers to redefine local agriculture to produce new environmentally friendly food and oil crops that would be competitive and attractive to an international clientele. The company planned to reinvest profits from the production of *Jatropha* back into its operations.

At the time, the growing of *Jatropha* for biofuel feedstock was being aggressively promoted in Kenya by the private sector and NGOs for its potential to grow well almost anywhere, be resistant to pests and unattractive to browsing animals.

Energy Africa collaborated with 100 farmers in the Shimba Hills area, on the south coast of Kenya, to grow *Jatropha* trees for oil production. The farmers were provided with seedlings, information on how to manage the trees, and assistance with pest control. The trees were intercropped on farmers land, mostly as a support for passion fruit vines and grown alongside maize, beans, and other vegetables and fruits.

The seeds produced by the farmers are bought by Energy Africa for a guaranteed minimum price. They are pressed and filtered at a small facility the company has in the Shimba Hills and sold to select tourist establishments in Diani beach as an ecofriendly lighting source in place of imported paraffin or diesel.

The partnership

When Energy Africa was establishing its operations in Kenya, they felt a need to partner with local organizations also interested in *Jatropha* production for biofuel. Informal partnerships were formed among the following:

- Energy Africa – *Jatropha* growing as a social business.
- Norwegian University of Life Sciences – joint learning on the viability of *Jatropha* production.

- World Agroforestry Center – joint learning on the viability of *Jatropha* production.
- Global Environment Fund project – technical collaboration.
- Deutscher Entwicklungsdienst (the German Development Service) – development of various *Jatropha* products, in particular oil lamps.

Energy Africa together with the World Agroforestry Center established a test plot of *Jatropha* for provenance trials to determine the best planting material for the local area. This proved to be an expensive and time-consuming undertaking for Energy Africa.

Successes

Energy Africa continues to support 60 smallholder farmers who are growing *Jatropha*. The company purchases the seed produced by the farmers at a fair price and processes it into oil for one large hotel and other buyers.

The partnership has had success in linking farmers with markets but not in the development of *Jatropha* as a viable commodity in Kenya. Energy Africa is operating at a loss with regard to *Jatropha*; however, their work in securing investors and establishing networks of farmers and local partners has enabled the company to establish a successful business in fruits and vegetables. They work with approximately 10 outgrowers in Shimba Hills and sell fresh produce to a growing local market.

Challenges

Energy Africa ventured into *Jatropha* growing when it was being promoted as easy to grow, with high returns anticipated for biofuel feedstock. The farmers they collaborated with had high expectations for the trees they planted.

The reality proved quite different. Little information was made available on the difficulties associated with growing *Jatropha*, production costs proved much higher than expected and yields were low. The 60 000 trees that are still grown produce just 2 ton year^{-1} of seed from two growing seasons.

A survey of yields by Iiyama *et al.* (2013) found 79% of farmers in Kenya growing *Jatropha* obtained just 0.1 kg of seed per tree and 41% of these obtained no seed at all. The low yields were due partly to the use of inferior germplasm as well as poor farm management and to the planting of *Jatropha* in inappropriate environmental conditions. The study urges against the growing of *Jatropha* by smallholders in Kenya until further research can determine how best to increase yields. It suggests that significant returns for Kenyan farmers – and a useful contribution to climate change mitigation – would only be possible with the coordinated introduction of more productive planting material that is environmentally matched to local conditions and the adoption of suitable farm management methods.

There was considerable outside interest in the activities of Energy Africa and the informal partnerships which were established prolonged the company's investments in *Jatropha*.

Initially the company produced soap and locally made *Jatropha* lamps that it hoped would be popular in the local market. These proved too costly for farmers so now only some lamps are manufactured on demand.

The company has since shifted to growing vegetables and fruit with outgrowers and relies more on the resources within the company and local knowledge than on time-consuming partnerships with major institutions.

Other Examples of PPPs Relevant to Agroforestry

Partnerships through PES schemes and in tertiary agricultural education are broadly discussed here as types of PPPs that have relevance to agroforestry.

Payments for Ecosystem Services

PES schemes may be viewed as a form of PPP whereby a buyer provides monetary or in-kind incentives to a provider to implement activities that maintain ecosystem services.

Trees in forests, woodlands, agroforests, and elsewhere provide important ecosystem services including soil, spring, stream and watershed protection, animal and plant biodiversity conservation, and carbon sequestration and storage; all of which can ultimately benefit local communities' livelihoods (Garrity, 2004). Individual farmers can be encouraged to preserve and reinforce these functions in agroforests through PES schemes which provide them with monetary or in-kind rewards for their efforts.

The United Nations' Millennium Ecosystem Assessment (2005) established that the natural resource base is declining partly due to the lack of mechanisms to value aspects of nature (Redford and Adams, 2009), assigned as public goods and excluded from market transactions. A conceptual framework of ecosystem services categorized as provisioning, regulating, supporting, and cultural was developed to guide the understanding of the value of nature in order to better manage it. PES acts as a mechanism to enable these nonmarket values of ecosystem services to be included in economic transactions as incentives for local actors to provide such services (Engel *et al.*, 2008).

PES is perceived to be efficient and fair because of its use of positive incentives to cause improved environmental service production. Because the beneficiary directly pays the environmental service providers, PES has potential to reduce donor dependence (Kumar and Muradian, 2009). PES exists in many different forms with different levels of conditionality, efficiency, and fairness (Wunder, 2005; van Noordwijk and Leimona, 2010; Swallow *et al.*, 2009).

Examples of effective schemes

In Costa Rica, upstream land owners are paid to retain forest cover and implement other catchment conservation practices using a compulsory fee charged on top of tariffs from downstream water users (Pagiola, 2006). It is implemented countrywide ensuring that all watersheds are sustainably managed.

A Wildlife Works project in Kenya pays landowners a lease with some restricted-grazing easement for restoration of a wildlife migratory corridor between two national parks. Revenue from avoided CO_2 emissions, through farmers no longer practicing forest-burning methods and instead managing pasture, is shared with landowners. Local communities also

benefit through employment in a garment factory run by the company involved in partnership with big brand companies.

The CARE-WWF project, Equitable Payments for Environmental Services in Naivasha, Kenya operated from 2006 to 2011. It promoted PES between upstream landowners and downstream flower irrigation farmers. By supporting start-up costs, through capacity building and provision of inputs, desirable conservation practices, such as grass strips and the growing of fruit trees, were established which also improve household incomes. The local benefits rather than the regular payment from the downstream buyers are driving farmer performance. Many more farmers are seeking to join the scheme, however, the buyers cannot afford to pay them all.

A similar project promoted PES in the subcatchment of the Mfizigo River in Uluguru Mountains of Tanzania. The scheme was aimed at provision of watershed services by more than 450 farmers upstream to buyers downstream (the Dar-es-Salaam Water and Sewerage Corporation and Coca Cola Kwanza Ltd.). Payments were allocated according to hectares of land converted and the type of conservation practice adopted. The scheme was briefly successful but is now experiencing challenges dues to leadership changes within the companies.

The partnerships

Almost all PES projects have been initiated by NGOs, and many evolve from existing conservation projects and build on existing networks to introduce PES as a new approach. Community members are generally engaged through meetings and policy makers through policy briefs, publications, and workshops. Various methods are used to determine communities' willingness to engage, such as reverse auctions and household surveys.

Private sector engagement is facilitated through iterative dialog to raise awareness and present potential business cases for engagement. Research organizations, such as the World Agroforestry Center, often partner with local implementers to provide evidence (household surveys, models, biophysical, and action research) of the potential for various conservation interventions and PES approaches to deliver the desired outcomes for different stakeholders in natural resource management. The provision of biophysical and socioeconomic tools also enables parties to dialog and develop agreements for PES.

PES successes and challenges

Most PES projects involve initial investment of donor funding in capacity building and dialog with stakeholders through NGOs.

The strongest driving force for a successful PES scheme is the existence of demand for the ecosystem service by beneficiaries who also have the capacity to pay. This demand can be voluntary, mandatory, or a combination of the two. Voluntary schemes coming from a perceived business case of using PES play a small role in the markets and are sometimes transient. For example, in the Mfizigo River catchment, once the personalities that believed in PES left the companies PES was abandoned (Tom Blomley pers. Comm). Public support, mainly through legislation, is essential to drive the demand for PES; for example, through legal assertion of a minimum standard with sanctions for noncompliance. Alternatively, it can enforce payments by embedding them into regular obligatory public fees or tariffs, which are then distributed to landowners on conditional delivery of the ecosystem service (e.g., Costa Rica – Pagiola, 2006).

A satisfactory payment that is guaranteed drives performance; for example, Singkarak, Indonesia and Ecotrust (Carter, 2009) but this can depend on the level of satisfaction perceived by the parties. A project in the Sasumua watershed in Kenya through the World Agroforestry Center's Pro-poor Rewards for Environmental Services in Africa program estimated a potential net annual saving of approximately US$20 000 in sediment treatment costs from PES with grass strips. This was perceived to be too small to persuade the downstream potential buyer, Nairobi Water and Sewerage Company, to engage in PES (Mwangi *et al.*, 2011).

PES engagement needs to be perceived by both buyers and sellers as mutually beneficial. When downstream beneficiaries invest in start-up costs for interventions that have potential for local business spinoffs, local engagement can be sustained without dependence on regular subsequent payments, for example, Wami Mbiki (Richards, 2009).

With regard to agroforestry, Roshetko *et al.* (2007a) observed that the most important factor in determining smallholders' tree planting and retention behavior is the direct products and services they receive from trees. Smallholder agroforestry systems have the advantage of not only providing wider ecosystem services but also directly producing other marketable products (Leakey, 2001, 2010).

PPPs in Tertiary Agricultural Education

PPPs are emerging in Tertiary Agricultural Education Institutions (TAEI) to overcome constraints that include: decreased funding leading to insufficient and degraded teaching facilities and materials (Buchert, 2002; Atteh, 1996; Rivera, 2006); depleted human resources due to brain drain and exodus of experienced staff to other professions (Maguire, 2000); HIV (Gakusi, 2010); and in some cases conflict situations. PPPs serve to address the limitations of human resources and facilities to accommodate increasing student numbers (Atteh, 1996).

In relation to agroforestry, as in other fields of agricultural science, partnerships between the private sector and publically funded tertiary institutions offer opportunities for joint research, innovation, greater funding, and improved dissemination of knowledge.

Through PPPs, universities benefit from enhanced student learning, research production, enhanced interdisciplinary research, the creation of innovation Kezar and Lester (2009), and faster technology transfer (Krattiger, 2007). They are also in a better position to access investments in laboratories and equipment, student scholarships and funding for graduate research (Ssebuwufu *et al.*, 2012), and more likely to receive external funding (Kvale and Brinkman, 2009).

The private sector can benefit from collaboration with universities through shared facilities, university offered services, access to the expertise of universities and spread of new knowledge. Ssebuwufu *et al.* (2012) observed that African universities can play a central role in producing and spreading technical solutions for local challenges. In situations where a large number of students are attached to an industry or research institution, this provides an inexpensive labor force and

can also generate innovation. Organizations partnering with universities may also have the opportunity to influence TAEI curricula so that it can better fit current needs.

The UniBRAIN program

UniBRAIN is one such PPP that is currently being implemented through consortia in five African countries, linking education, research institutions, and businesses with the aim of improving education systems within agriculture, fostering innovation, increasing production, and improving supply chains. Each consortium manages an incubator project and among them are projects aimed at supply chain development for commodities that include coffee, tea, honey, mango, banana, and other local fruits. The incubatees vary from start-up enterprises to small and medium enterprises as well as enterprises that are expanding, diversifying, or experiencing challenges. **Figure 3** provides a simplified diagram of relationships and benefits among UniBRAIN consortia members and incubatees.

Success in incubator projects relies on effective collaboration between all partners, and that each UniBRAIN member gains certain benefits from participation, such as:

- Universities: career-enhancing research and research opportunities for postgraduates; funding for on-campus research related to innovations; access to private enterprise and research communities; opportunities for student placements; support for curricula change; and fostering of linkages and interactions with nonAfrican universities and capacity building institutions.
- Private sector: specialized technical support; premises with facilities and services; and the receipt of student placements. The existence of incubators can address supply chain challenges in a very direct way, for example, a business start-up can be formed specifically to address one step in supply addition for an agroforestry commodity.
- Research institutions: partnerships with business for commercializing products and technologies; collaborators and temporary staff support through attachments and internships; and collaboration in research to combine human and physical assets (ANAFE, 2013; FARA, 2013).
- Incubatees: assistance with business and financial planning; specialized technical support; mentoring; and premises with facilities and services and the receipt of student placements.

In general, all partners benefit through UniBRAIN from greater efficiency, effectiveness, and improvement of governance and management. Tang *et al.* (2010) argues that

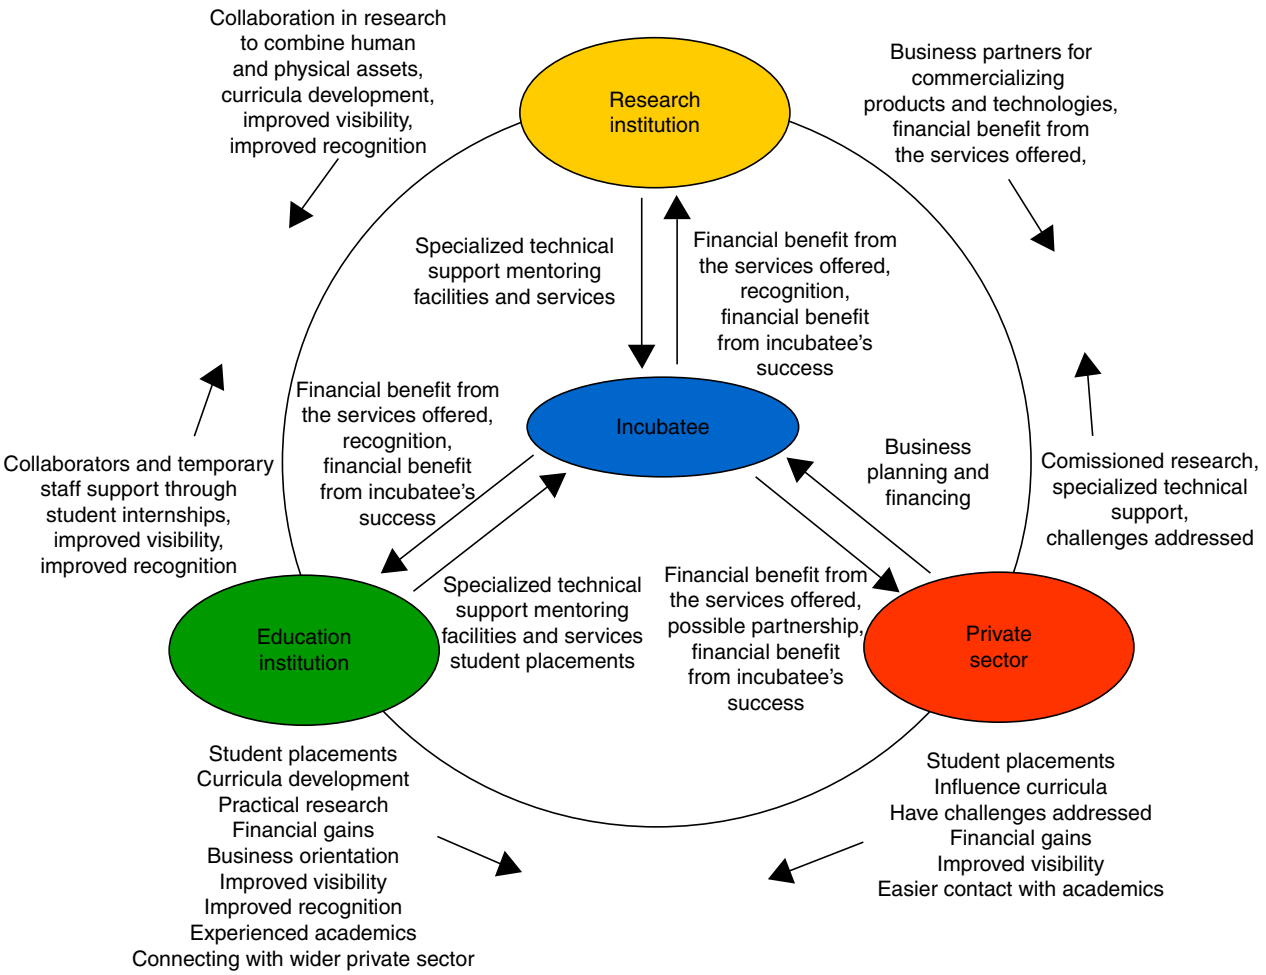

Figure 3 Simplified benefit flow among UniBRAIN members and incubatees.

UniBRAIN enables better risk management, clearer government policies, revealed critical success factors, improved maturation of contract, and more appropriate financial analysis.

Discussion

In agricultural research and development, PPPs are increasingly viewed as an effective way to conduct advanced research, develop new technologies, deploy new products for the benefit of smallholder farmers, and other marginalized groups in developing countries (Spielman *et al.*, 2007).

The PPPs in agroforestry profiled in this article can broadly be shown to be:

- Helping to lift smallholder farmers out of poverty through research and new technologies that improve the productivity and quality of agroforestry products and further develop new products.
- Helping farmers to benefit from market participation through establishing and improving the functioning of supply chains.
- Generating innovation through joint research.
- Integrating production with environmental management.

In the six case studies on PPPs in agroforestry analyzed for this article, poverty reduction was a central aim. The extent to which this is currently occurring or likely to occur in the future depends on the scale at which the partnership is operating, the particular product and the type of intervention. PES schemes that involve beneficiaries directly paying providers of ecosystem services are also geared toward poverty alleviation.

A number of the PPPs discussed in this article are helping to improve the functioning of supply chains and commercialize intermediary or underdeveloped agroforestry species; including: improving the marketing position of growers (rubber and mango), improving productivity (cocoa and *Allanblackia*) and expansion to meet demand (*Acacia*).

The PPPs concerning *Allanblackia* and cocoa provide examples of where private and public organizations are jointly conducting innovative research to develop and improve emerging and established agroforestry products. This is contrary to the findings of Spielman *et al.* (2007) whose analysis of PPPs in the CGIAR system did not find evidence of joint research on cutting-edge science with the private sector to generate innovation. Kezar and Lester (2009) found that universities can benefit from the creation of innovation through PPPs.

The partnerships in place to develop *Allanblackia*, cocoa, and rubber all incorporated strong elements of environmental management. These, together with PES schemes involving agroforestry, highlight the multipurpose nature of agroforestry in its ability to provide both commercial commodities as well as valuable environmental services.

Another potential impact of PPPs according to Spielman *et al.* (2007) is that they provide research organizations with insight into industry perspectives and change the way some centers do business, such as the shortest route to launching a product, the need to terminate projects when they fail to perform, and the importance of demand-side or market analysis. Although research organizations involved in the case studies presented here may be learning such approaches and in some cases adopting them, differences in the modes of operation between private and public organizations were often cited as challenges to the maintenance of effective partnerships.

Building Effective Partnerships in Agroforestry

The PPPs described in this article point to several factors that ensure partnership effectiveness, namely: agreement to a common goal, effective governance, monitoring, and the sharing of information. This supports the elements of a successful partnership outlined by Spielman *et al.* (2007): clear definition of the problem, its solution, and the resources needed to achieve the solution; establishment of benchmarks to gauge progress and decide on next steps; and effective communication channels to all key stakeholders through which to exchange knowledge, resolve conflicts, and change course as needed.

In nearly all cases, both public and private sectors were shown to be working toward a common goal in their partnerships.

Contracts, memorandums of understanding, steering, and technical committees were the common platforms for partnership management in the PPPs analyzed for this article. For a partnership to operate successfully, it was considered important to have a forum or system in place for addressing tensions or instances where one partner does not deliver on its obligations.

The monitoring of partnership progress in meeting medium- and longer term goals was deemed important under the majority of agroforestry PPPs and tended to occur at the strategic level.

Attipoe *et al.* (2006) suggest that open and constant communication between partners from different backgrounds is the only way to deal with misconceptions. This allows consensus to be reached and encourages innovation in reaching new solutions. At the technical level, information exchange in the agroforestry PPPs analyzed occurred primarily through meetings and reports. The potential for the withholding of information to threaten efforts and trust within partnerships makes information exchange a vital component to the success of any PPP.

Overcoming Obstacles in Agroforestry Partnerships

The main challenges associated with agroforestry PPPs covered in this article related to issues of difference in culture between private and public sector partners, investment of time and effort, overcoming risks, obstacles associated with public policy, and failures in reporting and delivery. Spielman *et al.* (2007) acknowledges that PPPs require contributions of knowledge from multiple actors across both time and space; contributions that are often difficult to manage and evaluate.

Although trust between private and public agencies is cited as an obstacle to PPPs – with Poulton and Macartney (2012) stating that it maytake time for private agents to gain trust in public sector partners – this did not appear to hamper the efforts in the agroforestry PPPs analyzed (**Table 2**). Private

Table 2 Goals, success factors, and challenges associated with public-private partnerships (PPPs) in agroforestry

		Allanblackia	*Cocoa*	*Rubber*	*Jatropha*	*Acacia*	*Mango*
Goals	Poverty reduction	x	x	x	x	x	x
	Market participation	x	–	x	–	x	x
	Innovation	x	x	–	–	–	–
	Environmental protection /management	x	x	x	–	–	–
Success factors	Common goal	x	x	x	x	x	x
	Governance	x	x	–	–	–	–

	Policy	x	x	x	–	–	–
	Reporting	x	x	–	–	–	–

sector culture varies from that of research institutions and the public sector in general. The private sector is often interested in quick returns on investments, whereas researchers are keen to ensure the validity of their results. Researchers have an interest in publishing results which can provide a challenge when the private sector is hesitant about research entering the public domain before they have benefited from their investment.

Experience gained by the World Agroforestry Center more than the past 15 years in finding the most effective balance between different activities for the promotion of a new tree crop has shown that a coordinated strategy is needed that incorporates market, cultivation, and conservation elements (Leakey *et al.*, 2005, 2007; Leakey and Akinnifesi, 2008; Tchoundjeu *et al.*, 2006). Crucially, this involves addressing the different perceptions of various specialists involved in particular areas of work. For example, those supplying goods to markets can find it difficult to understand why it takes so long to conduct the research needed to bring a species into cultivation for the first time. At the same time, cultivation specialists operating in the public sector have only limited insights into the commercial pressures of markets, and they prefer to continue their research until optimal rather than sufficient solutions – which would be adequate for the private sector – have been developed for planting and farm management. There is frequently skepticism among conservation specialists about whether private industry is committed to long-term sustainable production.

The time and effort required to maintain an effective partnership is considerable, and for the majority of those involved in the partnerships presenting in this article, seen as vital to effective future cooperation.

According to Spielman *et al.* (2007) PPPs, carry some very unique risks, including those associated with coordinating diverse partners and interests; protecting the mandates, missions, and reputations of partners; and exchanging proprietary knowledge assets between public and private sectors. In the PPPs analyzed, communication between partners and more broadly to other organizations and stakeholders, together with investment in activities that ensure the continued commitment of partners, are important strategies to mitigate these risks.

Enabling policies and political commitment can be a constraint to private investment in supply chains (Poulton and Macartney, 2012). Although acacia production in Vietnam has succeeded because of government investment and motivation, future high-level investment in the cocoa sector in Côte d'Ivoire will require further efforts in policy development.

Ineffective or reporting failures and failure to deliver on commitments were described as partnership challenges in some of the agroforestry PPPs analyzed. This underlies the importance of putting sound governance structures in place to address tensions and conflicts.

Future Potential for PPPs in Agroforestry

Spielman *et al.* (2007) note that the number of cases where PPPs are leveraging private investment in poorly functioning agricultural supply chains is still limited. This is contrary to the number of collaborative efforts to develop new technologies between public and private sectors in the health sector, catalyzed by health investment funds that in recent years have led to companies seeking new models of drug development that combine social responsibility and commercial viability (Poulton and Macartney, 2012).

Challenge funds in agriculture that disburse grants on the basis of periodic competitive bidding processes do exist, and according to Poulton and Macartney (2012) encourage or hasten investment with high social returns.

The reliance on donor funding in addition to private sector investment of several of the agroforestry PPPs analyzed supports the need for further funds within the field of agricultural research to catalyze PPPs. Similarly for PES schemes, donor funding has been required in the early stages to build capacity and dialog. Poulton *et al.* (2006) identified that investments by both private and public actors are required to support service delivery to staple food producers in Africa.

Increasing pressure on government budgets across the world, especially in developing countries, necessitates partnerships between the public sector and the private sector to allow risks and benefits to be appropriately shared. Private expenditure on agricultural research and development is

Box 1 Enabling PPPs in kenya

Kenya's increasing population has compounded the challenge of ensuring food security in the country. A history of land grabbing and successive subdivision of family holdings prompted an overhaul of Kenyan land regimes, including the introduction of a new Constitution in 2010 with significant focus on land issues, in particular ensuring the equity, efficiency, productivity, and sustainability of land in Kenya (National Council for Law Reporting, 2012). The Constitution sets out the principles of sustainable and productive management of land resources, sound conservation practices and protection of ecologically sensitive areas. New legislation in the form of PPPs Act 2013 has also been enacted to regulate the relationship between the Government's resources and private market's growth potential. Under the Act, PPPs are defined as arrangements between a governmental party and a private party under which a private party:

- undertakes to perform a public function or provide a service on behalf of the contracting authority,
- receives a benefit for performing a public function by way of: compensation from a public fund, charges or fees collected by the private party from users or consumers of a service provided to them, or a combination of such compensation and such charges or fees, and
- is generally liable for risks arising from the performance of the function in accordance with the terms of the project agreement.

PPPs under the Act may be proposed in one of the two ways. A governmental party may procure a PPP through the determination of a project and the initiation of a tender process in which private sector participants (either individually or through a consortium) may bid. Alternatively, a private party may initiate a 'privately initiated investment proposal' provided that the private party can determine that there is significant urgency, the private party has expensive or unique intellectual property rights attached to the project, or they meet any other criteria which the minister may prescribe. Though no criteria have been prescribed as yet, it is likely that these will include projects involving agroforestry.

The types of PPPs specified in the Act vary considerably and include arrangements whereby a private party could lease land, operate and manage a facility or concession, or perform services on behalf of a public authority. Depending on the nature of the PPP project, a number of the options provided for in the Act may be appropriate for use in agroforestry partnerships.

The recent legislative and constitutional changes in Kenya taken together are profound and create an enabling environment for agroforestry PPPs. In addition, in order for the Government of Kenya to undertake its constitutional obligations under Article 69, it would be desirable for the Government to mobilize private sector resources through PPP structures.

increasing in some developing countries with greater domestic and global market opportunities, progress in the development of advanced agricultural technology, and stronger regulatory regimes that favor private investment (Pray and Fuglie, 2001; Pray, 2002). The introduction of the PPP Act in Kenya is one example of an initiative that may well open up new opportunities for private investment in agriculture (see **Box 1**).

In agroforestry, there are intermediary and underdeveloped products that have considerable potential with greater investment and private sector involvement. Ofori *et al.* (2013) believe the PPP for the domestication of *Allanblackia* provides a good model for the domestication of a traditionally important forest tree species of high economic potential which could be expanded to species, such as baobab, tamarind, and the medicinal species *W. ugandensis* and *Prunus africana*.

Ultimately, PPPs in developing-country agriculture are about reducing poverty by providing smallholders and other vulnerable social groups with new technological options. The case studies in this article reveal the potential for a variety of partnership approaches to be adopted in the development of new agroforestry commodities or to improve the market supply and functioning of supply chains for established agroforestry products to alleviate poverty.

Acknowledgment

The authors thank the following for their contributions in compiling the case studies included in this article: Christopher Harwood, Nobuko Kato, Christophe Kouame, Beria Leimona, Daniel Ofori, Jeroen Oostenenk, Cornelia Roettger, Josef Toledano, and Eirik Jarl Trondsen; and Sara Namirembe and Marta Zdravkovic for information regarding PES schemes and PPPs in tertiary agricultural education. The authors are also extremely grateful to Ian Dawson for his extensive comments on earlier versions of this article.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Critical Tracking Events Approach to Food Traceability.

> *See also*: Agribusiness Organization and Management. Food Chain: Farm to Market. Food Labeling. Food Law. Food Packaging. Food Security: Development Strategies. Food Security: Food Defense and Biosecurity. Food Security, Market Processes, and the Role of Government Policy. Food Security: Postharvest Losses. Global Food Supply Chains. Government Agricultural Policy, United States. Regulatory Conventions and Institutions that Govern Global Agricultural Trade

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Agriculture and People

Agribusiness Organization and Management
Agricultural Cooperatives
Agricultural Ethics and Social Justice
Agricultural Finance
Agricultural Labor: Demand for Labor
Agricultural Labor: Gender Issues
Agricultural Labor: Labor Market Operation
Agricultural Labor: Supply of Labor
Agricultural Law
Agricultural Policy: A Global View
Analyses of Total Phenolics, Total Flavonoids, and Total Antioxidant Activities in Foods and Dietary Supplements
Changing Structure and Organization of US Agriculture
Climate Change, Society, and Agriculture: An Economic and Policy Perspective
Computer Modeling: Policy Analysis and Simulation
Consumer-Oriented New Product Development
Crop Insurance
Determining Functional Properties and Sources of Recently Identified Bioactive Food Components: Oligosaccharides, Glycolipids, Glycoproteins, and Peptides
Farm Management
Food Chain: Farm to Market
Food Labeling
Food Law
Food Marketing
Food Security, Market Processes, and the Role of Government Policy
Food Security: Development Strategies
Food Security: Food Defense and Biosecurity
From Foraging to Agriculture
Global Food Supply Chains
Government Agricultural Policy, United States
Human Nutrition: Malnutrition and Diet
Industrialized Farming and Its Relationship to Community Well-Being
Intellectual Property in Agriculture
International and Regional Institutions and Instruments for Agricultural Policy, Research, and Development
International Trade
Investments in and the Economic Returns to Agricultural and Food R&D Worldwide
Markets and Prices
Mathematical Models to Elaborate Plans for Adaptation of Rural Communities to Climate Change
Policy Frameworks for International Agricultural and Rural Development
Production Economics
Quantitative Methods in Agricultural Economics
Regulatory Conventions and Institutions that Govern Global Agricultural Trade
Rural Sociology
Safety of Street Food: Indonesia's Experience
Social Justice: Preservation of Cultures in Traditional Agriculture
Vitamins and Food-Derived Biofactors

Agriculture and the Environment

Agroforestry: Conservation Trees and Erosion Prevention
Agroforestry: Hydrological Impacts
Air: Confined Animal Facilities and Air Quality Issues
Air: Greenhouse Gases from Agriculture
Biodiversity and Ecosystem Services in Agroecosystems
Biodiversity: Conserving Biodiversity in Agroecosystems
Climate Change: Agricultural Mitigation
Computer Modeling: Applications to Environment and Food Security
Crop Pollination
Dust Pollution from Agriculture
Ecoagriculture: Integrated Landscape Management for People, Food, and Nature
Economics of Natural Resources and Environment in Agriculture
Energy and Greenhouse Gases Footprint of Food Processing
Land Use: Catchment Management
Land Use, Land Cover, and Food-Energy-Environment Trade-Off: Key Issues and Insights for Millennium Development Goals
Land Use: Management for Biodiversity and Conservation
Land Use: Restoration and Rehabilitation
Linkages of the Agricultural Sector: Models and Precautions
Market-Based Incentives for the Conservation of Ecosystem Services in Agricultural Landscapes: Examples from Coffee Cultivation in Latin America
Natural Capital, Ecological Infrastructure, and Ecosystem Services in Agroecosystems

Soil: Carbon Sequestration in Agricultural Systems
Soil: Conservation Practices
Soil Greenhouse Gas Emissions and Their Mitigation
Soil: Nutrient Cycling
Virtual Water and Water Footprint of Food Production and Processing
Water: Advanced Irrigation Technologies
Water Use: Recycling and Desalination for Agriculture
Water: Water Quality and Challenges from Agriculture
Weather Forecasting Applications in Agriculture
World Water Supply and Use: Challenges for the Future

Agriculture Products

Advances in Pesticide Risk Reduction
Agricultural Mechanization
Agroforestry: Complex Multistrata Agriculture
Agroforestry: Fertilizer Trees
Agroforestry: Fodder Trees
Agroforestry: Participatory Domestication of Trees
Agroforestry: Practices and Systems
Asian Aquaculture
Beef Cattle
Climate Change: Animal Systems
Climate Change: Cropping System Changes and Adaptations
Climate Change: Horticulture
Climate Change: New Breeding Pressures and Goals
Critical Tracking Events Approach to Food Traceability
Dairy Animals
Edaphic Soil Science, Introduction to
Fermentation: Food Products
Fermented Beverages
Food Engineering
Food Microbiology
Food Packaging
Food Safety: Emerging Pathogens
Food Safety: Food Analysis Technologies/Techniques
Food Safety: Shelf Life Extension Technologies
Food Security: Postharvest Losses
Food Security: Yield Gap
Food Toxicology
Forage Crops
Global Agriculture: Industrial Feedstocks for Energy and Materials
Green Revolution: Past, Present, and Future
Medicinal Crops
Organic Agricultural Production: Plants
Organic Livestock Production
Precision Agriculture: Irrigation
Public–Private Partnerships in Agroforestry
Root and Tuber Crops
Sensory Science
Simulation Modeling: Applications in Cropping Systems
Slum Livestock Agriculture
Small Ruminants in Smallholder Integrated Production Systems
Spices and Aromatics
Sugar Crops
Terroir: The Application of an Old Concept in Modern Viticulture
Tree Fruits and Nuts

Animal Health

Animal Health: Ectoparasites
Animal Health: Foot-and-Mouth Disease
Animal Health: Global Antibiotic Issues
Animal Health: Mycotoxins
Animal Health: Tuberculosis
Animal Welfare: Stress, Global Issues, and Perspectives
Biosecurity and Equine Infectious Diseases
Detection and Causes of Bovine Mastitis with Emphasis on *Staphylococcus aureus*
Emerging Zoonoses in Domesticated Livestock of Southeast Asia
Invasive Aquatic Animals
Marek's Disease and Differential Diagnosis with Other Tumor Viral Diseases of Poultry
Poultry and Avian Diseases
Quarantine and Biosecurity
Swine Diseases and Disorders
Vaccines and Vaccination Practices: Key to Sustainable Animal Production
Zoonotic Helminths of Livestock

Plant Health

Climate Change and Plant Disease
Emerging Plant Diseases
Integrated Pest Management in Tree Fruit Crops
Invasive Species: Plants
Mineral Nutrition and Suppression of Plant Disease
Pathogen-Tested Planting Material
Plant Abiotic Stress: Salt
Plant Abiotic Stress: Temperature Extremes
Plant Abiotic Stress: Water
Plant Biotic Stress: Weeds
Plant Disease and Resistance
Plant Health Management: Biological Control of Insect Pests

Plant Health Management: Biological Control of Plant Pathogens
Plant Health Management: Crop Protection with Nematicides
Plant Health Management: Fungicides and Antibiotics
Plant Health Management: Herbicides
Plant Health Management: Pathogen Suppressive Soils
Plant Health Management: Soil Fumigation
Plant Health Management: Soil Solarization
Quarantine and Biosecurity
Soil Fertility and Plant Nutrition

Agriculture and Science

Advances in Animal Biotechnology
Agbiotechnology: Costs and Benefits of Genetically Modified Papaya
Biotechnology Crop Adoption: Potential and Challenges of Genetically Improved Crops
Biotechnology: Herbicide-Resistant Crops
Biotechnology: Pharming
Biotechnology: Plant Protection
Biotechnology: Regulatory Issues
Breeding: Animals
Breeding: Plants, Modern
Cloning Animals by Somatic Cell Nuclear Transplantation
Cloning: Plants – Micropropagation/Tissue Culture
Domestication of Animals
Domestication of Plants
Genebanks: Past, Present, and Optimistic Future
Genomics of Food Animals
Genomics: Plant Genetic Improvement
Heterosis in Plants
Plant Cloning: Macropropagation
Plant Virus Control by Post-Transcriptional Gene Silencing
Regulatory Challenges to Commercializing the Products of Ag Biotech
Stem Cells
Transgenic Methodologies – Plants

PREFACE

Food is absolutely necessary for human existence, yet for most in wealthy nations it is largely taken for granted because of its abundance. Sufficient food is a concern, however, for about 1 billion of the earth's inhabitants today who often go to bed hungry. Food security in a broad sense is becoming a worry of the future for those who understand the limitations of our earth's ecosystems. Malthusian prophecies have so far been wrong, but there is growing concern that we are rapidly reaching the point where feeding the world's growing and richer population will be at the cost to our environment that is unacceptable. In the next few decades we face the challenge of growing more food, with less water, with less fertilizer on less land – because of the growth of urban areas on prime agriculture land. We also face the largely unknown consequences that global warming will have on agricultural production. During the last century agricultural scientists were able to bring cutting-edge science into traditional agricultural practices and increase food production sufficiently to prevent global food shortages. The hope that new scientific discoveries will provide the means to keep ahead of world food demand is complicated by a growing public discomfort with biotechnology being applied to food production.

The concept of services being provided by the ecosystems of the earth is a fairly recent attempt to understand and place value on functions of natural lands that have historically been assumed to have few limits. In the past, if more food was needed, new lands were converted from forests or steppe lands into farm land and new water systems developed to provide the water needed for agriculture. When human populations were low our activities were largely buffered by the abundance of forest and steppe, but too late, we are beginning to understand that these provisioning services of our ecosystems are being overused and are no longer buffered by the abundance of wild lands and waters. We are rapidly losing our planet's biodiversity, irreplaceable ground water is being unsustainably consumed, and major river systems are being overused and polluted. Our oceans, the last place on the planet that still support our hunter and gathering traditions may not be able to sustain these activities into the future. And, food production and processing activities contribute to the greenhouse gas emissions that are rapidly warming our planet. Agriculture is the single greatest user of the earth's land and water resources. In the concept of ecosystem services, provisioning or providing food for all organisms is one of the services provided by ecosystems. Human population growth has and will continue to overtax the ecosystems we inhabit. The ultimate outcome of this major diversion of nature's resources into provisioning the human species is unknown, but it is critically important for us to understand what we must do to sustain our planet.

The breakthrough discovery about 10 000 years ago that plants and animals could be bred to provide a more abundant and secure food source was the foundation upon which all other human activities were able to flourish. Activities other than finding food now became possible and our diverse cultures were able to develop because of agriculture. Until fairly recently, however, the majority of the population of most nations was still directly involved in producing food. Mechanization of agriculture and continued improvements in genetics, fertilizers, and pesticides made food production very efficient in developed nations. In the United States, the leading nation in value of agricultural exports, less than 2% of the workforce is currently employed in producing food. The United States, however, is alone among the most populous nations of the world in having such a small population employed as farmers. In countries such as China, India, Indonesia, and Nigeria the majority of people are rural and involved in agriculture either directly or indirectly. But, as food production becomes more efficient in these countries, and as wages increase in other sectors, a major shift is occurring from rural to urban occupations. This revolution is potentially as important in affecting our cultures and community structures as was the development of agriculture. Many nations are currently experiencing a very rapid transition from rural to urban living with all of the social and logistic problems associated with such rapid structural changes. While this transition in our social and cultural structures is a broad subject, it does have significant impacts on agriculture and our food systems. To mention just a few, agriculture labor, food transport, food safety, and access to healthy food.

There is genuine concern among agricultural scientists that human populations and changing diets are outpacing our ability to meet the increasing food needs of the planet. In the first iteration by Academic Press in 1994 of the *Encyclopedia of Agricultural Science*, Noble Prize Winner Normal Borlaug wrote in its forward:

> Had the world's 1990 food production been distributed evenly, it would have provided an adequate diet (2350 calories, principally from grains) for 6.2 billion people – nearly one billion more than the actual population. However, had the people in Third World countries attempted to obtain 30% of their calories from animal products – as in the United States, Canada, or European Economic Community countries – a world population of only 2.5 billion people could have been sustained – less than half of the present world population.

The issue raised by Dr. Borlaug is probably the most important challenge we face. Human behavior and the food choices of consumers will determine the outcome of the race between food supply and population. Population control has been advocated for decades, and in some cases has become part of national policy, but the world's population continues to grow. Science breakthroughs cannot solve our food security and environmental quality challenges if consumers reject food that is not traditionally produced. Likewise, if meat products and other inefficiently produced food continue to be in high demand by consumers, there will be increased pressure on our food production systems. As supplies become short, prices rise. While this may be good for farmers, high food prices and food shortages will probably undermine our efforts to preserve the

world's remaining arable land as natural lands. We must change human behavior to solve the problems we face.

Food choices, nutrition, diets, food cultures, water and air quality, GMOs, global warming, food security, and similar topics are daily in the news throughout the world. We are all concerned about these issues, yet with all of the information easily available in the popular media about food there seems to be too little informed discussion on these various topics. In planning the *Encyclopedia of Agriculture and Food Systems* the editorial committee chose to organize the topics primarily by issues, rather than to focus on a traditional topic approach. We organized the issues that would be discussed in the chapters around the broad topics of Agriculture and People, Agriculture and the Environment, Agricultural Products, Plant Health Management, Animal Health Management, and Agriculture and Science. The issues raised in this preface are the ones that we felt needed to be addressed in this encyclopedia.

The associate editors joined me in the development of topics for the encyclopedia and were responsible for working with the authors – they deserve particular recognition. I was fortunate to be joined by a very distinguished group of colleagues who, I hope, are still friends. They spent much more time and effort in bringing this project to completion than any of us anticipated. I want to thank our authors who while overly committed and overworked, fulfilled their commitments to contribute to this work. I have been impressed with the quality of their contributions. The editorial staff of Elsevier have had the professionalism and patience to work with scientists who do not work under the same time and budget constraints that the staff work. I want to particularly thank Kristi Gomez, Donna de Weerd-Wilson, and Simon Holt who, each in succession, oversaw this effort, and I especially thank the project managers, who worked directly with me, and the associate editors, Kate Miklaszewka-Gorczyca, Will Bowden-Green, and Sam Mahfoudh.

Glossary

Computable general equilibrium These models are a class of theoretically based economic models that simulate the reaction of an economy to various changes in terms of prices, production, factor use, household income, and other items.

Econometrics Is the term given to a set of statistical and mathematical techniques used to analyze empirical data. Generally, econometric analysis aims at quantifying economic theories, testing hypotheses, forecasting future values of economic variables, and quantifying the effects of alternative government, firm, or individual decisions on economic outcomes.

Hypothesis tests They are statistical techniques used to determine whether or not a specific conjecture is supported by a particular data set. Hypothesis tests are formally stated as a null hypothesis that the specific conjecture is true and an alternative hypothesis that the conjecture is not true. A test statistic is constructed from observed data assuming that the null statement is true and the hypothesis is rejected if the calculated test statistic exceeds a critical level for its known distribution.

Linear programming Is a special case of mathematical programming where the objective function is linear as are the restrictions on the decision variables.

Mathematical programming It refers to a class of problem-solving techniques where one is trying to find the appropriate values of a set of decision variables so that an objective is optimized while obeying a set of restrictions on the allowable decision variable values.

Operations research It refers to the application of mathematics and the scientific method to decision making with the intent to improve the design and operation of the system studied.

Regression analysis Is a statistical tool for quantifying the relationship of one or more independent/explanatory variables to a dependent variable. Properly implemented, regression analysis can be used to determine a probabilistic statement of the extent to which changes in explanatory variables are related to changes in the dependent variables. The most commonly used regression technique is ordinary least squares.

Simulation It refers to a problem analysis method where one develops a computerized model of a system then uses that model to depict the reaction of the system to different operating decisions and/or levels of external stimuli.

Simultaneous equations They refer to econometrically estimated multiequation systems involving multiple interdependent variables. In simultaneous equation models, several dependent, or endogenous, variables are jointly determined by a set of explanatory, or exogenous, variables and error terms. Each equation may have one or more endogenous variables and one or more exogenous equations.

Introduction

Generally, agricultural economists use quantitative methods for three purposes. First, quantitative methods can be used in conjunction with observed data to discover how individuals behave when confronted with various economic stimuli and, in cases, to test the accuracy of economic theory. Second, quantitative techniques can be used to forecast economic trends and project the consequences of alternative decisions. Third, quantitative techniques can be used to resolve choices among decision alternatives. The methods employed for satisfying the above purposes can be broadly classified into econometric techniques that focus primarily on model estimation and hypothesis testing, and operations research (OR) techniques that are most commonly applied in agricultural economics research to optimization and simulation and often utilize model parameters obtained using econometric methods.

Econometric Estimation

Econometrics is concerned with describing and evaluating the relationship between a target variable, called the dependent variable, and one or more explanatory variables, often called independent variables or regressors. Under certain conditions a causal relationship is presumed from the explanatory variable

to the dependent variable and an equation is estimated in which the dependent variable is expressed as a function of the independent variables. However, many analyses are concerned with systems of simultaneous equations where independent variables influence a set of dependent variables, which also influence each other. In either case, economic theory and empirical observation guide the model specification and method of estimation. For general treatments of econometric modelling, see for example, Judge *et al.* (1985), Maddala and Lahiri (2009), Wooldridge (2010) and Greene (2011).

The basic ingredients in an econometric model are an assumed functional relationship between the dependent variable and the independent variables and an error term that allows deviations between predicted values of the dependent variable and its observed values. A widely used econometric model incorporates a linear functional relationship between the dependent variable and independent variables, along with an additive error term. This model is given as:

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 x_{3i} + \ldots + \beta_k x_{ki} + e_i,$$

where, for the ith observation, y_i is the dependent variable, x_{1i}–x_{ki} are the independent variables, e_i is the stochastic error term or disturbance, and β_0–β_k are unknown parameters. The regression problem generally involves finding the β's so that some function of the error terms across the observations is minimized. Alternative functional forms can be used to express the relationship between the dependent variable and the independent variables and, generally, the error term need not be additive.

A model specification is not complete without specifying the characteristics of the error term. There are two main sources of randomness incorporated in the error term: unpredictable randomness in human behavior and the effects of a large number of unimportant omitted variables. It is commonly assumed that the error term has a mean value of zero and an equal finite variance for all observations.

Given data for the dependent and independent variables, the objective of econometrics is to obtain estimates for unknown parameters β_0–β_k. To achieve this goal, certain prerequisite conditions (assumptions) must be met. These assumptions vary depending on the estimator selected, but the following are commonly used.

1. The expected value (mean) of e_i is zero (i.e., $E(e_i)=0$, for all i, where i indexes the number of observations in the data set).
2. The variance of e_i is equal for each observation (i.e., $V(e_i)=\sigma^2$, for all i).
3. The explanatory variables x_1–x_k are nonstochastic (i.e., the explanatory variables are presumed to be determined from forces outside the equation and not related to the error term e_i).
4. Each explanatory variable contributes a unique influence on the dependent variable y (i.e., the explanatory variables are not perfectly multicollinear).
5. The model is correctly specified.

The first assumption is not restrictive. The second assumption is sometimes referred to as homoskedastic errors. Homoskedasticity can be violated in two distinct ways. First, the variances in error terms can be correlated across observations such that the probability of a positive error in one observation influences the error in adjacent observations. When the data are for sequential time periods (called time series data), this is referred to as serial (or auto) correlation, or more generally, intertemporal dependence. Second, the variances can differ by observation depending on the values of some subset of the explanatory variables. This condition is termed heteroskedasticity and is most common in cross-sectional data, which invoke observations across individuals or firms. The third assumption is sometimes referred to as fixed regressors. It implies that the explanatory variables come from an experimental process where the investigator sets the level of the independent variables and then observes the outcomes of the dependant variables; a rare occurrence in economic modeling. In fact, the explanatory variables can be stochastic so long as the distribution of the error term does not depend on any explanatory variable. The fourth assumption implies that the data representing the explanatory variables are not perfectly multicollinear; i.e., there is not an exact linear relationship among any subset of the regressors. The fifth assumption implies that the correct functional form is truly linear, that the model contains all relevant variables, but does not include any irrelevant variables, and that the model has an additive error.

Although it is not necessary, another commonly used assumption is that the error term is normally distributed. In small samples, statistical inference (hypothesis testing) is based on assumed normality of the error term. If sample size is large, approximate normality for inference can be established through the central limit theorem.

Each of these assumptions can be relaxed to obtain estimates of the unknown parameters β_0–β_k, and variance of the error term, σ^2. In addition, the validity of each assumption can be determined using appropriate hypothesis tests.

Empirical Estimation

Econometric estimation uses available data plus any additional information about the probability distribution of the error term to provide estimates of unknown model parameters, which form the predictive equation. The true, but unknown, parameter values are called population parameters. Parameter values obtained from data are called estimates. The criterion for obtaining parameter estimates from data is called the estimation method or simply an estimator.

Because estimation methods employ functions involving data that include the dependent variable, which by assumption contains error, the resultant parameter estimates are random variables. Only by coincidence will an estimated parameter estimate equal its 'true' population value, but as random variables, parameter estimates have sampling properties. Evaluating estimators' distributional properties amounts to characterizing their sampling distributions.

Desirable estimator properties

Unbiasedness means that if a parameter is estimated repeatedly from different data samples, the average value of the estimated parameter will equal the underlying population parameter. An estimator is efficient if it is unbiased and has no

greater variance than any other alternative unbiased estimator. Unbiasedness and efficiency are small sample properties that can hold for all sample sizes. But, if any assumption discussed in the Section Econometric Estimation is violated, unbiased, and hence, efficient estimators are not available. In such cases it is customary to apply estimators with desirable large sample properties. Consistency ensures that as sample size expands, the probability of an estimator being close to its true parameter value will increase. Sufficient conditions for consistency are that bias and variance both tend toward zero as sample size expands. Asymptotic efficiency is the large sample analog of finite sampling efficiency. An estimator is asymptotically efficient relative to any other if it is a consistent estimator and the variance of its limiting distribution is smaller than that of any other consistent estimator.

Some commonly used estimators

Estimators can be grouped into one of three categories: minimum distance estimators (including the most common technique, ordinarily least squares regression), maximum likelihood estimators, and method of moment estimators.

The commonly used ordinary least squares (OLS) criterion is a minimum distance criterion that produces parameter estimates that minimize squared prediction errors. Given a data sample of T observations, the least squares estimator obtains values for β_0–β_k that minimize the sum-of-squared residuals.

$$S = \sum_i e_i^2 = \sum_i (Y_i - \hat{Y}_i)^2,$$

where

$$\hat{Y}_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \ldots + \beta_k X_{ki}$$

OLS offers two major advantages over alternative estimators. First, it does not require specifying the error term's underlying distribution. Second, if assumptions 1–5 are met, OLS parameter estimates are unbiased and efficient.

Maximum likelihood estimation yields estimates of the unknown parameters that have the largest probability of giving rise to the sample that was actually selected. Maximum likelihood estimation requires assumption of a particular probability distribution function for the error term and computes the probability of the sample occurrence. The resultant equation is the probability function of the dependent variable outcome as a function of the values of the unknown parameters. Maximum likelihood estimates are those resulting from maximization of this function with respect to parameters to be estimated. When the error term is normally distributed, the maximum likelihood estimator is the same as the method of moments and OLS estimator just discussed. Under fairly general conditions, maximum likelihood estimators are consistent and asymptotically efficient.

Method of moments estimators simply replace population parameters with their sample counterparts. For example, the sample mean can be substituted for the population mean. A more general family of estimators, called general methods of moments (GMM) estimators, offers a flexible framework of econometric modeling. Compared with the maximum likelihood estimators, GMM estimators do not require distributional assumptions and therefore provide a viable alternative especially when plausible or manageable distributional assumptions are not available.

Statistical inference

Many times the investigator is only interested in estimating parameters for forecasting or simulation. Other times, the purpose of analysis is to test whether a particular independent variable is a significant factor in the equation for the dependent variable. In these cases estimates can be useful in their own right. In addition, more advanced hypothesis tests can be constructed that answer the question of whether the observed difference between a function of the estimated parameters and some hypothesized value is real or is due to chance variation. In application, test statistics are used to check hypothesis tests. Test statistics are based on estimated parameters and their sampling distribution. Two simple test statistics appropriate in small samples and when the error term is normally distributed are the t-test and F-test. The t-test is used to test a hypothesis concerning a single parameter (e.g., is β_0 statistically different from zero?) and is constructed as the ratio of an estimated parameter to its standard error. The F-test is used to test the truth of multiple parameter restrictions such as does a subset of the β's sum to zero and is constructed as the adjusted percent loss in sum-of-squared predicted errors from imposing a hypothesized linear restriction on a group of parameters.

Three more hypothesis testing procedures are available to test the truth of multiple parameter restrictions: Wald, likelihood ratio, and Lagrange multiplier (score) tests. The Wald test and score test can generally be implemented using any estimation procedure, but the likelihood ratio test requires maximum likelihood parameter estimation. The Wald test requires estimating only the unrestricted model and specifying the hypothesized restriction. This can be advantageous when the restricted model is difficult or impossible to compute. The likelihood ratio test requires estimating both the restricted and unrestricted model parameters. The likelihood ratio test statistic is computed as the ratio of the likelihood function evaluated at the restricted parameter estimates and the likelihood function evaluated at the unrestricted parameter estimates and hence is easy to implement when both the restricted and unrestricted models can be estimated. The score test requires estimating only the restricted model. Under the null hypothesis all three test statistics are distributed according to a Chi-square distribution with degrees of freedom equal to the number of parameter restrictions imposed. The null hypothesis is rejected when calculated test statistic values exceed critical values associated with a chosen level of significance.

Lastly, if the asymptotic distribution of a test statistic is overly complicated or one is concerned about the reliability of large sample approximation, there exist inference methods based on resamplings, such as the bootstrap and Jackknife methods. These methods are generally more reliable in finite sample settings, albeit computationally expensive.

Violation of Model Assumptions

In application, the assumptions stated above may be violated. In this section each model assumption will be considered

from three perspectives: (1) How can the validity of each assumption be checked? (2) How are the parameter estimate sampling properties altered if a particular assumption is violated? (3) What alternative estimators can be used to obtain desirable parameter estimates when standard techniques are inappropriate?

Homoskedastic errors

So far it has been assumed that the error terms are homoskedastic; the error terms have common variance at each observation. One possible violation of homoskedasticity is heteroskedasticity. Heteroskedastic errors have different variances and generally occur in cross-sectional data. An often cited example of heteroskedasticity comes from household savings models. In any particular time period, households can use earnings for consumption or savings. Suppose savings are modeled as a function of income. Low-income households must spend nearly all income on consumption items, but high-income households can consume or save. As a result, high-income households exhibit greater variance in savings than do low-income households. The error term in predicting savings is therefore generally found to be correlated with income. Under heteroskedastic errors, the OLS estimator is still unbiased, but it is not efficient. More importantly, estimated parameter variances from OLS are biased, invalidating significance tests and hypothesis testing.

A number of tests are available for detecting heteroskedasticity. Tests involve examining whether residuals from a regression are significantly affected by values of independent variables either through a second regression of the error term on a function of the independent variables or by examining whether groupings of the error terms for different ranges of the dependent variables have statistically different variances.

Estimation methods may be altered to correct for heteroskedasticity. Generalized least squares (GLS) estimators use a three-step estimation process to obtain efficient parameter estimates. First-round OLS estimation is used to compute error terms at each observation, then these errors are squared and regressed on the independent variables. The dependent variable and independent variables are then divided by the square root of estimated variance for each observation and OLS estimation is reapplied to the transformed data. GLS estimators are biased in small samples but they are consistent and asymptotically efficient.

Autocorrelation of residuals is another phenomenon that invalidates the homoskedasticity assumption. Autocorrelation occurs when error terms are correlated; i.e., when error term e_i is correlated with error terms e_{i+1}, e_{i+2},..., and e_{i-1}, e_{i-2},..., and so on. One explanation for autocorrelation is that factors omitted from the model are correlated across time periods. Autocorrelation results in unbiased but inefficient parameter estimates and makes hypothesis testing inappropriate. The most widely used test for autocorrelation is the Durbin–Watson test. It is based on OLS residuals and is appropriate for testing first order autocorrelation – correlation between e_i and e_{i-1} – when the model does not contain lagged dependent variables. Similar tests are available for testing higher-order autocorrelation and for testing autocorrelation in the presence of lagged dependent variables.

Maximum likelihood and GLS estimators are available that correct for autocorrelation. The GLS estimator involves transforming the data to correct for autocorrelation and then obtaining second-round parameter estimates using OLS. The data transformation requires estimating the correlation between error terms from OLS residuals, transforming the data to eliminate correlation between errors, and reestimating the transformed model using OLS.

Stochastic or endogenous regressors

Until now, it has been assumed that each model contains a single endogenous, or dependent variable; all other variables appearing in the model are independent or exogenous. This assumption is sometimes referred to as 'fixed regressors.' The crucial assumption is that each explanatory variable is independent of the error term, i.e., that random changes in the error term are not associated with changes in the explanatory variables. If this condition is not satisfied, the OLS estimator is both biased and inconsistent.

The fixed regressor assumption can be violated in two ways. First, an explanatory variable can be measured with error that is correlated with the disturbance term. Second, the economic system being examined may involve simultaneously determined 'endogenous' variables appearing as independent variables. Such variables are necessarily correlated with disturbance terms appearing in each equation. The classic example in agricultural economics models is a supply-and-demand model where price, quantity supplied, and quantity demanded are simultaneously determined. Consider a simple demand-and-supply model:

$$q_d = a_0 + a_1 p + a_2 I + e_d, \text{ demand function}$$

$$q_s = b_0 + b_1 p + b_2 C + e_s, \text{ supply function}$$

and

$$q_d = q_s, \text{ market identity}$$

where p is market price, q_s is quantity supplied, q_d is quantity demanded, I is income, C is production cost, a_0–a_2 and b_0–b_2 are unknown parameters, and e_s and e_d are stochastic error terms. Here p, q_s, and q_d are endogenous variables whereas I and C are the exogenous variables. Equilibrium price, quantity supplied, and quantity demanded can be obtained as the solution to the system of equations. A change in production cost, C, shifts the supply function causing a change in equilibrium price and quantities. Similarly, realization of an external shock through either error term reveals itself through a change in equilibrium quantities and price. As a result, price and quantities are stochastic variables that are correlated with the error terms in each equation. Both supply and demand are functions of price, a stochastic variable correlated with the error terms; hence, OLS is an inappropriate estimator for the unknown parameters. Before estimation can be considered, the fundamental question of whether the unknown parameters of interest in a simultaneous equations model are estimable must be addressed. The question that arises is: given information about the underlying model structure, is more than one theory, or set of equations, consistent with the same data? If so, the two models are observationally equivalent and

model parameters cannot be estimated. This issue is referred to as the econometric identification problem. For linear models, a necessary, but not sufficient, condition for parameter identification in any equation is that the total number of exogenous variables excluded from the equation must be at least as great as the number of included endogenous variables, less one. This result is known as the order condition of identification. A necessary and sufficient condition for parameter identification is given by the rank condition. In simultaneous equations models, each equation must be checked for econometric identification before any estimation technique is applied.

A general method for obtaining consistent parameter estimates when stochastic regressors are a problem is the instrumental variable (IV) method. An IV is one that is uncorrelated with the error term but is correlated with the explanatory variables in the equation. In the simultaneous equations model above, income would be a good instrument for price in the supply equation and production cost would be a good instrument for price in the demand equation. One special IV estimator is two-stage least squares (2SLS). 2SLS estimation is achieved by applying OLS in two stages. First, OLS is used to obtain predicted values for each endogenous variable using all exogenous variables in the system as explanatory variables. Second, endogenous explanatory values are replaced with their predicted values and OLS is used to obtain parameter estimates. 2SLS is a biased but consistent estimator; it is not efficient. Asymptotically efficient estimation must account for potential correlation among error terms across equations at the same observation. Systems estimators account for cross-equation correlation of error terms and are asymptotically efficient. Three-stage least squares is an IV type systems estimator. Maximum likelihood estimators are also available for simultaneous equations systems.

Hausman's specification test is a very general hypothesis test that can be constructed to detect endogenous variables. An OLS estimator is both consistent and efficient when the explanatory variables are exogenous, but is inconsistent in the presence of endogenous explanatory variables; in contrast, the IV estimator is consistent regardless of the endogeneity problem, but less efficient than the OLS estimator in the absence of endogenous variables. Hausman's test is based on the comparison between the OLS and IV estimators. The presence of endogenous variables cannot be rejected when the two set of estimates are significantly different.

The testing for and handling of endogeneity plays a fundamental role in modern econometrics, which strives to distinguish association from causal inferences. The former refers to functional or statistical relationships among multiple variables, whereas the latter indicates that a change in one factor is responsible for corresponding change in another variable. The main obstacle to establishing a causal relationship in social science such as economics is the endogeneity problem wherein both the explanatory variable and outcomes may be determined simultaneously, sometimes by other (confounding) factors. The IV approach is a popular method to tackle the endogeneity problem. Alternatively, one can use methods in the program evaluation literature, such as matching, propensity score, regression discontinuity, for causal inferences.

Multicollinearity

Multicollinearity is the term used to describe a problem that occurs when the independent variables are linearly dependent, i.e., when one or more independent variables can be exactly explained as a linear function of other explanatory variables. Multicollinearity causes one to be unable to isolate the individual effects of explanatory variables and leads to inflated variances in the estimated parameters. The problem is most extreme when each explanatory variable does not exert an independent effect on the dependent variable resulting in a situation of perfect multicollinearity where model parameters cannot be estimated. Multicollinearity appears most often in time series data where observations on the variables are over a number of time periods. Tests and corrective procedures for multicollinearity, such as ridge regressions, principal component analysis, and regularization methods, are available, but generally result in biased parameter estimates.

Functional form

Obviously, the adequacy of an estimated equation is greatly influenced by the choice of functional form. There are three important considerations in making such a choice. These are: (1) not excluding explanatory variables that should be included; (2) excluding superfluous explanatory variables; and (3) specifying an exact functional relation between the independent variables and the dependent variable. Exclusion of relevant explanatory variables results in biased and inconsistent parameter estimates and renders hypothesis tests inappropriate. Including extraneous explanatory variables results in loss of efficiency but does not induce bias in parameter estimates. Inappropriate functional form results in biased and inconsistent parameter estimates. Various model selection hypothesis tests are available for detecting whether or not an explanatory variable should be included in a model and the appropriateness of the assumed functional form.

Instead of imposing a fixed functional form, a flexible alternative is to let data determine the functional relationship between the dependent variables and independent variables. This approach is called nonparametric estimations. Popular nonparametric estimators include the kernel regression methods, spline regression methods, and neural networks. These methods are generally guided by some data-driven principles with the objective of minimizing certain loss criteria such as the mean square errors. Compared with parametric methods such as the OLS, nonparametric methods are more flexible albeit less efficient.

Special Situations

A number of special situations require alternative estimation methods. Three important situations occur with limited dependent variable models, nonstructural time series models, and panel data models.

Limited dependent variable models

There are many situations where the dependent variable of interest involves a yes or no, 1 or 0, outcome. Such models are called limited dependent variable or qualitative choice models. For instance, in analyzing farmer participation in

government programs one might have data on whether or not any particular farmer participated, along with explanatory variables for expected returns from participating and expected returns from not participating. Parameter estimates for models involving binary dependent variables are obtained using limited dependent variable estimation methods. In such a case, the outcome of the discrete choice is viewed as a reflection of an underlying continuous valued index function

$$y_i^* = \beta_0 + \beta_1 X_{1i} + \ldots + \beta_k X_{ki} + e_i,$$

where y_i^* is an unobservable index representing farmer i's desire to participate in the government program. The estimation technique is based on an assumed distribution and an approach that maximizes the probability of producing the decisions actually observed in the sample. The unknown parameters are typically estimated using either the probit model assuming the errors are normally distributed or the logit model when the errors are assumed logistically distributed. Both models are widely used and in practice there is little difference in the estimation results.

The regression coefficients from either model cannot be directly interpreted as the marginal effect of the associated explanatory variable on the dependent variable as is generally the case in linear models. The marginal effect of any explanatory variable on the probability of a yes decision outcome of the dependent variable is:

$$\partial E\frac{[y]}{\partial x_i} = f(\beta_0 + \beta_1 X_{1i} + \ldots + \beta_k X_{ki}).\beta_i,$$

where $f(.)$ if the probability density function of the error term.

Similar methods are available for other kinds of limited dependent variable models. For instance, multinomial logistic or probit models are commonly used to model multiple choice (e.g., mode of transportation), Poisson or negative binomial models are used for counting data (e.g., number of traffic incidents), and Exponential or Weibull models are used for duration analysis (e.g., length of unemployment).

Time-series models

Economic Time Series Analysis refers to the study of economic data observed in time sequence. Here, order of the observations is an important consideration, as the economy (e.g., agricultural economy) is viewed as evolving through time. The position of the economy in the past has something to say about its current and future position. Early work in this area studied univariate processes (representations for a single series of data, say wheat prices). The single series of data (X_1, X_2, …, X_T) is said to be covariance stationary if it returns to its historical mean and variance/covariance in a finite number of observations. Formal tests of nonstationary data were developed by Dickey and Fuller (1979), others followed in the literature. Here the null hypothesis in the series is nonstationary. If one fails to reject this null, usual practice is to consider the process that generates the first time difference of the series ($w_t = X_t - X_{t-1}$, $t = 2,\ldots,T$). If one rejects the null hypothesis of nonstationary on X_t, analysis is confined to the original series X_t. The number of differences is referred to as the order of integration and represented as $I(0)$ for no differences, $I(1)$ for 1 difference, etc. In economics it is common to find price series are integrated of order 1 (i.e., they are $I(1)$). Following the influential work of Box and Jenkins (1976) the series X_t or the stationary-induced series (w_t) can be parsimoniously modeled as an autoregressive integrated moving average (ARIMA) process:

$$\Phi(B)(1-B)^i X_t = \Theta(B)e_t,$$

where $\Phi(B) = (1-\varphi_1 B^1 - \varphi_2 B^2 - , \ldots , \varphi_p B^p)$ is a polynomial in the lag operator (B) such that $B^i X_t = X_{t-i}$ (post multiplying B^i by X_t takes p back in time i periods); $\Theta(B) = (1-\vartheta_1 B^1 - \vartheta_2 B^2 - , \ldots, \vartheta_q B^q)$; and e_t is a white noise innovation term ($E(e_t = 0)$ and $E(e_t, e_{t-k}) = 0$ for $k \neq 0$ and σ^2 for $k = 0$). The variables p and q in the above representation are finite integers, 0, 1,...,. Empirical work oftentimes finds these to be 0, 1, or 2. Specifying the orders p and q was originally accomplished by studying the autocorrelation and partial autocorrelation functions on data separated by k periods. More recent work studies statistical loss metrics, following Akaike (1971).

Generalization of the ARIMA representation over several variables ($X_{1,t}, X_{2,t}, \ldots, X_{M,T}$) has been studied as a vector ARIMA representation (Reinsel (1997)). Here X is indexed by both t ($t = 1,\ldots,T$) and m ($m = 1,\ldots,M$). Economic theory (or other relevant information) is used to select the set of M variables to study. Although the general Vector Autoregression-Moving Average (VARMA) representation is of some interest, most analysis is confined to the Vector Autoregression (VAR) or Vector Error Correction (VEC) process – arguing that the moving average components of the VARIMA representation can be approximated by a high-order autoregression. Sims (1980) introduced economists and agricultural economists to the VAR form and Engle and Granger (1987) introduced economists to the VEC form. The VAR and VEC forms summarize the correlation properties in contemporaneous and lagged time among the levels of the multiple time series (a levels VAR), their first differences (a VAR in first differences), or mixtures of levels and first differences (VEC). Here the Dickey–Fuller test of nonstationarity (or one of its alternatives) plays an essential role in model specification.

Early versions of multiple time series representations were labeled as atheoretic, as they placed few, if any, *a priori* restrictions on how the data interact in contemporaneous or lagged time. As such, they were heavily used in forecasting. More modern adaptations of the VAR and ECM forms look for structural restrictions on the contemporaneous innovations, garnering the former the label structural VAR (Sims, 1986). Structural VARs are often used in policy settings. Adaptations of structural VARs with statistical dimension reduction techniques and factor VARS are used in settings where the number of series (M above) is large (Bernanke *et al.*, 2005).

The parameters of the univariate ARIMA and the multivatiate VARIMA forms can be estimated by maximum likelihood methods. If we constrain our study of the VARIMA form to the VAR with every variable in every equation (what is known as the unrestricted VAR) OLS, estimated equation by equation can be used for efficient estimation. If one considers VARs where some variables are not included in the lag representations of other variables (a subset VAR) seemingly unrelated regressions provide efficient parameter estimates (Hsiao, 1979). The ECM is generally estimated with maximum

likelihood methods following Johansen (1988). A two-step procedure for a two variable ECM is described by Engle and Granger (1987).

Panel data models

Panel data refers to the type of data in which multiple units are observed for more than one period (Wooldridge, 2010). For example, if a household or farm survey follows the same set of households or farms for multiple periods, it is called a panel or longitudinal study. Panel data offer opportunities and challenges, both arising from the presence of unit-specific effects. Suppose each unit in a panel data has a time invariant individual effect, observing the same unit overtime allows researchers to account for the influence of unobserved individual effects, which is not feasible if each unit is observed only once. However, the pooled OLS is generally not efficient because of the individual effects, which violate the independence assumptions of the error terms. There exist two estimation methods that account for the individual effects: the fixed effects estimator and the random effects estimator. The former estimates the individual effects using dummy variables for the units, or removes the individual effects via demeaning or first differencing. The latter treats the individual effects as random parameters and uses an error component approach to construct a GLS estimator wherein the variance covariance matrix reflects the influence of individual effects. Generally the random effects estimator is more efficient, but is restrictive because it requires that individual effects are not correlated with the explanatory variables.

Operations Research Techniques

The field of OR is a broad one. Virtually all of the techniques in the field have been employed in agricultural economics applications. However, the most common applications involve mathematical programming and simulation.

Mathematical Programming

Mathematical programming is used to solve the problem of finding the best decision strategy from a set of allowable decisions constrained by scarce resources, minimum requirements, and other considerations. The mathematical representation of this problem is:

$$\begin{aligned} &\text{Max} \quad f(x) \\ &g_1(x) \leq b_1 \\ &g_2(x) \geq b_2 \\ &g_3(x) = b_3 \\ &x \geq 0, \end{aligned}$$

where the set of possible decisions is depicted by X, $f(X)$ is an algebraic expression of the objective to be maximized by the choice of X. The X decisions represent a set of nonnegative possibilities, which must also satisfy the constraints defined by the $g_i(X)$ functions. Here, each of the $g_i(X)$ and b_i relations are vectors so that multiple restrictions are potentially defined by each constraint equation plus some can be null so only particular types of constraints may be present. The solution to such a model contains information about the optimum values of the decision variables (X) as well as information on whether constraints are restrictive. Solution information is also provided, which tells how much the objective function would change with changes in the constraint constants (b_i).

A common use for such models involves the choice among production alternatives so as to maximize firm profits subject to resource availability limits. However, many applications involve objectives that are designed to simulate economic behavior (i.e., maximizing agricultural sector consumers'/producers' surplus yields a solution simulating a perfectly competitive agricultural sector).

The linear programming problem

The linear program (LP) is a special case of the above problem where all the functions are linear. In the LP context, the model becomes

$$\begin{aligned} &\text{Max} \quad CX \\ &A_1X \leq b_1 \\ &A_2X \geq b_2 \\ &A_3X = b_3 \\ &X \geq 0 \end{aligned}$$

Here, X is a vector of decision variables, whereas C gives the contribution of one unit of the decision variables to the objective function, and A_1, A_2, and A_3 give the usage of each constraining item by each decision variable.

There are two types of assumptions underlying the use of such a formulation. The first set of assumptions are mathematical and indicate that: (1) returns and constraint effects are strictly proportional to the level of the variables (proportionality); (2) there are no interaction terms between the variables (additivity); (3) the X values are continuous with fractional parts allowed (continuity); and (4) all parameters are known with certainty (certainty).

The second type of assumptions involves the model's ability to portray the actual decision problem. These are that the objective function, variables, and constraints are appropriate.

The linear programming model is the most common mathematical programming technique and can be applied to a wide range of problems. Consider two examples. First, suppose one is trying to decide on a least cost livestock diet while satisfying the animal's nutrient needs. An LP formulation of that decision problem involves minimization of feed cost (the objective function) whereas the variables depict the amount of ingredients, such as corn and soybeans, purchased. Simultaneously, the constraints impose dietary nutrient (e.g., calorie and protein) requirements that must be met (e.g., Saxena and Chandra, 2011; Masset *et al.*, 2009). Second, suppose one is trying to predict how one might coordinate operations across a food supply chain. In that case, LP formulations might be assembled depicting operation of different firms across that chain. The models then could be used to examine the gains from coordination and the effects see the review in Ahumada and Villalobos (2009).

Much of the mathematical programming literature reflects attempts to appropriately formulate LPs for different situations and ways of relaxing the LP assumptions to investigate the effects of the various model assumptions.

Relaxing linear programming assumptions

The following discussion elaborates on the character and relaxation of the LP assumptions.

- Proportionality
  The assumption in linear programming that the objective function value and the resource usage be strictly proportional to X is commonly relaxed both within and outside of linear programming. The LP-based techniques deal with cases where there are diminishing returns to scale. These techniques basically involve specifying multiple variables that represent the effects of the nonproportional phenomena over different ranges of activity. Thus, one might specify a variable that earns a $2.00 return for selling the first two units of firm output with a constraint limiting sales to two, then another variable selling an additional two units at $1.50, etc. This involves incorporating multiple variables and constraints with resulting discrete jumps in returns and/or costs. It is also possible to model a continuous change in returns by using more general nonlinear programming techniques. The most common involves techniques called quadratic programming (QP). This technique only relaxes objective function proportionality. The QP objective function is

$$\text{Max } cx + x'Qx,$$

  where $x'Qx$ reflects interactions between variables and negative entries on the diagonal of Q reflect declining returns to increases in X. One common application of this involves incorporating demand and supply functions into formulations.

  Proportionally can also be relaxed in the constraints by using multiple variables or through the use of general nonlinear programming techniques.
- Additivity
  The additivity assumption prohibits interactions among variables. Thus, the quantity of one commodity cannot affect the marginal returns or resource use of another commodity. This assumption can be relaxed within linear programming by specifying multiple activities, but its formal relaxation requires nonlinear programming techniques. QP formulations are commonly used to allow objective function interactions. Namely, when the off diagonal elements in the above defined Q matrix are nonzero then there are interactions between variables. Relaxation of the additivity assumption within the constraints requires the use of general nonlinear programming where, for example, production could be modeled as a nonlinear function of multiple inputs given that the inputs individually and collectively reflect diminishing returns to scale.
- Certainty
  The certainty assumption requires that the modeler assert that each and every parameter in the model is known without question. This is quite often unrealistic in that parameters in agriculture are often subject to weather variations and other random events. The most common way of relaxing the assumption involves the parameters in the objective function. Concepts from financial portfolio theory have been adapted where decision makers are assumed willing to reduce expected return to achieve a reduction in the variance of return. This is usually modeled within the QP model where the constant terms reflect average returns to X and the Q matrix reflects a measure of risk aversion times the variance covariance matrix of returns.

  There are many additional modeling techniques for handling other forms of uncertainty. Typically, the models depict reactions to uncertainty such that a conservative strategy is followed (e.g., one might maximize variability discounted returns while being limited by variability deflated resource availabilities). Uncertainty models also reflect varying assumptions about how uncertain events arise. The key differentiating factor involves the interrelation of decision timing and uncertainty resolution. Nonsequential models assume decision makers commit themselves at the beginning of the year and then discover the uncertain outcomes at the end of the year. Sequential formulations (commonly called stochastic programming with recourse) model an interrelated stream of decisions and uncertainty resolution. For example, when modeling an agricultural operation in a sequential setting, planting decisions are made under planting and harvesting season uncertainty but harvesting decisions are made with knowledge of what happened during planting season (e.g., see Chen and McCarl, 2000).
- Continuity
  The continuity assumption allows any variable to take on any value including fractional values. However, certain variables may only make sense if they take on discrete values. This is commonly the case when one is modeling capital investment where equipment must be purchased in whole units. If this is the case, then integer programming must be used. Integer programming restricts the values of certain of the decision variables to have integer values thus prohibiting fractional values.
- Appropriate objective function
  The final commonly relaxed assumption involves the choice of a single appropriate objective function. This assumption is relaxed by using multiobjective programming techniques, which define a set of several simultaneous objectives. When using this technique one simultaneously models all the objectives and establishes goal preferences under an assumed utility function structure. The portfolio model discussed in the Section Relaxing linear programming assumptions is the most common example of this approach where expected returns maximization and variance minimization are the two objectives. Such models are also common in developing country applications of model and in technology development settings (see Lee *et al.*, 1995 or Pohekar and Ramachandran, 2004).

Duality

An important aspect of mathematical programming involves duality. The solution of a model actually yields two types of

information: (1) allocation data involving both solution levels of the variables and quantities of resource usage and (2) valuation (or duality) data involving both valuation of constraint resources and estimates of the costs of forcing variables into the solution.

The duality information gives the objective function implications of a right hand-side alteration. Often this is interpretable as a resource value. For example, in a model maximizing profits subject to land and labor constraints, then the duality output would tell how much profits would increase with more land and labor. Duality information would also be present in a cost-minimizing diet model indicating the marginal costs of meeting dietary nutrient constraints. Solution valuation data are called the shadow prices and are found in all MP outputs.

The duality information also gives indications of how much it costs to force unutilized variables into the solution. For example, in a diet model, if a particular feedstuff was not used, the model would contain information indicating the cost of forcing the use of that feedstuff.

Other programming methods

The above review, by its nature, is an overview and does not cover many possible programming techniques. Other techniques include:

1. Analytical programming methods wherein solutions are characterized in an abstract fashion to gain theoretical insight into problem solution properties. In such a setting the theories involving duality, Lagrangian multipliers, Karush–Kuhn–Tucker conditions, and optimal control are relevant.
2. Dynamic programming and optimal control theory methods, which are concerned with optimizing multiperiod problems.

Simulation

Another commonly used OR technique is computer simulation. However, this technique, unlike the Mathematical Programming or Econometric techniques discussed above, does not have a fixed structure. Simulation models may use *ad hoc* functions, theoretically derived functions, and/or econometrically derived functions. The models may incorporate numerically based or mathematical programming-based techniques. Further, one may simulate certain or uncertain systems. Simulation has been used in many settings; worth brief mention here involve econometrically based, firm financial-, process-, biophysical-, and programming-based. The econometrically based simulations include cases where an econometric model with dynamic properties is simulated over time under, for example, alternative policies. The firm financial simulations depict wealth, debt, as set accumulation, etc., under differing firm decisions and/or policy environments. The process-based simulations depict firm performance under changes in firm characteristics (e.g., truck congestion at a grain elevator as affected by new dumping capacity). The biophysical-based simulations depict plant or livestock growth under differing management and environmental regimes. The programming-based simulations use mathematical programming models to depict reactions of the modeled entity to alterations in parameters caused by the firm investment, the environment, or policy alterations. Given this wide variety of uses, a rigorous discussion of simulation techniques is not possible in this short space; rather the reader is referred to the Survey of Agricultural Economics Literature.

Computable General Equilibrium

Computable general equilibrium analysis generally refers to a situation where a whole economy is modeled and one incorporates commodity price formation, total production, household consumption, household income formation, income, price-related consumption demand, factor price formation, factor supply, intermediate goods consumption, and factor/commodity price-dependent production. The overall model is generally set up to simulate an overall equilibrium in the product and factor markets with household consumption driven by household income and intermediate consumption driven by an input–output (social accounting) matrix. A set of simultaneous nonlinear equations characterizes this equilibrium (see Dixon and Jorgenson (2012) or Burfisher (2011) for broad coverage). Such models are typically applied in settings where the items being studied have broad implications across the economy or where agriculture is a dominant sector. Both of these settings involve major implications for household income and in turn consumption. From an agricultural viewpoint, applications often involve highly aggregate representation of agricultural commodities (sometimes all goods, other times groupings into major classes like grains, oilseeds, livestock, and other), regions, and factors (often capital and labor with some representing land, water, and fossil fuels). Hertel (2002) discusses the character and relaxation of such representations. Computable general equilibrium is a complex broad field and readers wishing details are referred to Burfisher (2011), Hertel (2002), Dixon and Jorgenson (2012), and Löfgren *et al.* (2001).

Using Quantitative Techniques

Quantitative methods are applied in agricultural economics as a means of achieving an end. As such, the authors close with a discussion of how the methods reviewed are used in the three problem settings mentioned at the beginning of the article.

First, let us consider the use of quantitative methods to discover information about the influence of certain factors. In such cases, econometric techniques are commonly used to fit functions based on observable data. The accompanying statistical significance tests allow investigation of whether particular items significantly influence our ability to predict behavior and whether the influences conform with economic theory. However, the line between the techniques is blurred as it is quite common at present to develop econometric estimates using mathematical programming techniques. It is also common to use programming, computable general equilibrium, and simulation models in a comparative statics setting to see how certain policy, resource, or other changes influence economic outcomes.

The second problem posed above involved forecasting economic trends and the consequences of decisions. Econometric techniques are most amenable to forecasting future values of various economic items of interest. For example, one may construct a forecast of the near term inflation rate. However, as the time frame gets longer and more variables become involved in the process, one needs to move toward simulation. Econometrical simulation forecasts are most appropriate where the forecasted behavior is felt to be reasonably extrapolated from the past observations used in forming the econometric model. Forecasts from programming computable general equilibrium and noneconometric-based simulations are relevant when the extrapolation of past behavior is not felt to be in order. However, the use of such techniques requires adoption of a considerably larger set of assumptions. Namely, under the econometric technique one must choose independent variables and functional form whereas under the other techniques all the data must be specified as well as the objectives or market clearing conditions pursued, the functional forms, the variables, and the constraints. Nevertheless, if one assumes that an OR model adequately represents the decision situation, then one can use it to predict the consequences of things that alter model data. This includes forecasts of the consequences of technological change, environmental change, alterations in farm policy, and new equipment investments.

The traditional role of mathematical programming, computable general equilibrium, and simulation models is widely felt to be in the third problem setting where one is trying to resolve choices among decision alternatives. However, this is not the most common use of such techniques in agricultural economics. Usually these models are not adequate enough to directly resolve choices but rather are used as decision-making aids and forecasting tools identifying the consequences of select developments or decisions. Finally, such models are commonly supported by data derived through econometric or simulation-derived estimates of parameters.

Glossary

Containment The application of phytosanitary measures in and around an infested area to prevent spread of a pest.
Control (of a pest) The suppression, containment, or eradication of a pest population.
Emergency action A prompt phytosanitary action undertaken in a new or unexpected phytosanitary situation.
Entry (of a pest) The movement of a pest into an area where it is not yet present, or present but not widely distributed and being officially controlled.
Eradication The application of phytosanitary measures to eliminate a pest from an area.
Incursion An isolated population of a pest recently detected in an area, not known to be established, but expected to survive for the immediate future.
Introduction (of a pest) The entry of a pest resulting in its establishment.
Outbreak A recently detected pest population, including an incursion, or a sudden significant increase of an established pest population in an area.
Pest Any species, strain, or biotype of plant, animal, or pathogenic agent injurious to plants or plant products. Note: In the International Plant Protection Convention, plant pest is sometimes used for the term pest.
Pest-free area An area in which a specific pest does not occur as demonstrated by scientific evidence and in which, where appropriate, this condition is being officially maintained.
Pest risk (for quarantine pests) The probability of introduction and spread of a pest and the magnitude of the associated potential economic consequences.
Pest risk management (for quarantine pests) The evaluation and selection of options to reduce the risk of introduction and spread of a pest.
Quarantine The official confinement of regulated articles for observation and research or for further inspection, testing, or treatment.
Surveillance An official process which collects and records data on pest occurrence or absence by survey, monitoring, or other procedures.

Introduction

Biological security or biosecurity is a set of measures that protect the economy, environment, and community from harm from pests and diseases. This can be simplified to safeguarding of resources from biological threats (Sharma *et al.*, 2008). Biological threats can be defined as any organism (including biological material) that has the potential to harm people's health and life, food and agriculture, the environment, and the economy. Biosecurity encompasses all policy, planning, legislation, science, and underpinning operations to minimize the introduction, establishment, spread, and impact of harmful organisms that pose threat to our resources.

An Internet search for the word 'biosecurity' provides over a million hits with several definitions that may vary in scope and priority but their intent is broadly very similar. Biosecurity is a more proactive concept, a multilayered approach, a shift from zero risk to managed risk, from barrier prevention to border management (Beale *et al.*, 2008).

Quarantine versus Biosecurity

Border quarantine is an integral component of biosecurity. The term 'quarantine' has its origin in the Italian word '*quarantina*,' which means 40-day period and is largely associated with isolation, segregation, and disinfestation at the border. It includes a period of time during which the carrier of a suspected harmful organism is detained generally at a port of entry under enforced isolation to prevent the harmful organism from entering a country. It is an enforced isolation or restriction of free movement imposed to prevent the spread of the harmful organism.

The term 'biosecurity' is much broader in scope than quarantine. The origin of the term 'biosecurity' is not known; however, according to New Zealand's publication Biosecurity Issue 35 (May 2002) …New Zealand's Biosecurity Council chair John Hellstorm can take credit for coining use of the word biosecurity from his days at the Ministry of Agriculture and Forestry when a term was being sought for what eventually became the Biosecurity Act 1993. …The word acceptable to all the interested parties and the rest, as they say, is history. …It should be noted, though, the international use of the word biosecurity is still limited.

Bioterminology

The term biosecurity is often used in the same context as biosafety, bioterrorism, and in some instances biodiversity (biological diversity). The four terms are also often interchanged, with some believing that they have the same meaning, when in actual fact both biosafety and bioterrorism are parts of biosecurity, whereas biosecurity aims to protect biodiversity.

Biosafety refers specifically to the safety procedures and containment requirements associated with working with certain biological material. It includes products arising from biotechnology, such as living modified organisms. For example, as a biosafety measure, scientists working on the Ebola virus are required to adhere to strict biosafety regulations to ensure that they are not exposed to the virus and to prevent its escape from the laboratory.

Bioterrorism generally refers to the deliberate introduction or misuse of biological organisms or their products with the aim of causing harm. For example, the deliberate introduction of a biological organism into a food supply chain would be considered bioterrorism. The broader management of the bioterrorism event (containment, eradication, detection, diagnosis, risk assessment, and mitigation) falls within the scope of biosecurity.

The Convention on Biological Diversity (CBD) defines biodiversity as the variability among living organisms from all sources including terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems. Effective biosecurity is an important requisite for the conservation of biodiversity. Preventing the introduction and spread of invasive species including pests, diseases, and other organisms through biosecurity measures is important, not only for food security and agricultural health, but also links directly with the prevention of biodiversity loss (Outhwaite, 2010).

Globalization and Biosecurity

There are approximately 70 000 pest species and diseases that damage agricultural crops worldwide (Pimentel, 2009). Many of these pest species and diseases are localized in distribution. The likely consequences of globalization raise significant biosecurity concerns because of the unprecedented increase in the movement of goods and people, which can be potential carriers of pest species and diseases. Approximately 1 billion people travel internationally and over 8 billion tons of goods are transported via sea and air routes every year. The danger of globalization is the potential for international and intercontinental distribution and establishment of harmful organisms in different ecological regions. Incidents of infectious diseases appear to be increasing.

The plant sector, the source of food and feed worldwide, is facing increasing outbreaks of pests and diseases that significantly diminish food production and availability. There are frequent reports of detections of new pests or diseases in different parts of the world. Stem rust of wheat (caused by the fungus *Puccinia graminis* f. sp. *tritici* Ug99 strain), citrus greening (caused by three strains of the bacterium *Candidatus Liberobacter*), Pierce's disease (caused by the bacterium *Xylella fastidiosa*) of grapevine, citrus canker (caused by the bacterium *Xanthomonas axonopodis*), zebra chip disease of potato (putatively caused by the bacterium *Candidatus Liberibacter solanacearum*), and Varroa mite (*Varroa destructor*) pest of honeybee are just a few examples of threatening pests and diseases spreading to new regions during the past 15–20 years.

With the massive increase in movement of people and goods, accompanied by climate change, an increase in the emergence of new pest and disease threats is inevitable. Named plant viruses have risen from less than 380 species in 1991 to more than 1000 species today (Brendan Rodoni, personal communication). There is enhanced potential for the dispersal of potential pest species, creating fresh opportunities for them to move to new geographical regions, find new vectors, new hosts, new environments, and new opportunities for some to hybridize and form new species, strains and biotypes. Exotic invasive pest species and diseases are estimated to cause a US$ 1.4 trillion loss per year worldwide (Pimentel *et al.*, 2001). These pest and disease-induced losses are likely to increase significantly if potential pest species and diseases continue to spread to new regions. As such losses are much higher in developing countries, which lack effective biosecurity systems to safeguard their plant and animal resources from pests and diseases.

Drivers Underpinning Biosecurity

The three key drivers that underpin biosecurity are the economy, the environment, and social factors.

Economic drivers reflect the impact pests and diseases can have from a commercial perspective, including farm production losses (crops, meat, and milk), trade (import and export), and market access. Pest and disease incursions can affect the ongoing supply of agricultural products to the domestic market, and the commerce associated with the entire supply chain is also at risk. For example, an exporting country must show that their product is of acceptable quality to the importing country, which includes being able to demonstrate that the products are free of the pests and diseases appearing in the regulated pest and disease list of the importing country.

Environmental drivers include the impact that pests and diseases can have on both the natural and built environments. This includes natural ecosystems (flora and fauna), amenity (parks and gardens etc.), sustainability of crops and land for cropping, and buildings and infrastructure. Most pests and diseases have at least some commercial impact, but many also cause environmental problems and it is difficult to estimate their economic impact. For example, in 2009, the US Forest Service estimated that throughout the US approximately 169 million acres of forested habitat with maple species is vulnerable to attack from Asian longhorned beetle (ALB), Anoplophora glabripennis (Motschulsky). The estimated maximum potential national urban impact of ALB is a loss of 34.9% of total canopy cover, 30.3% tree mortality (1.2 billion trees) and value loss of US$ 669 billion (Nowak *et al.*, 2001).

Social drivers are those that may affect our social or psychological well-being and include the destruction of growers' crops or farm viability, loss of recreational facilities (e.g., walking/hiking trails), and food availability (food security). Consider the effect that destruction of a crop that is affected by a pest or disease might have on a growers' annual (or longer term) income. Lifestyle and livelihoods are not something that most people would consider when they think of a pest or disease; however, these must be taken into consideration when assessing the impact a pest or disease may have.

The International Biosecurity Framework

Globally, biosecurity is governed by several international agreements. The International Plant Protection Convention (IPPC) covers the protection of plants and plant products, animal biosecurity is governed by the World Organization for Animal Health (Office International des Epizooties; OIE), and international public health (human biosecurity) falls under the World Health Organization (WHO). As biosecurity underpins trade, the World Trade Organization's (WTO's) Sanitary and Phytosanitary (SPS) Agreement applies to all SPS measures that may, directly or indirectly, affect international trade. These measures must be developed and applied in accordance with the provisions of this agreement. In addition, through the framework of the CBD there is an increasing interest from the environment sector in utilizing existing standards, capacity, and expertise, when it is relevant to invasive species in the environment. Governments that are signatories must abide by the obligations outlined in these agreements or conventions.

Animal Biosecurity

The importance of animal diseases and their control led to the creation of the OIE through an international agreement signed in 1924. In 2003 the Office became the World Organization for Animal Health but kept its historical acronym OIE. The OIE is the intergovernmental organization responsible for animal health and biosecurity worldwide. It is recognized by the WTO and in 2012, has a total of 178 member countries and territories. The OIE maintains permanent relations with 36 other international and regional organizations and has offices on every continent. The mission of the OIE is to guarantee the transparency of animal disease status worldwide; to collect, analyze, and disseminate veterinary scientific information; to provide expertise and promote international support for the control of animal diseases; and to guarantee the sanitary safety of world trade by developing rules for international trade in animals and animal products.

Plant Biosecurity

The IPPC is an international plant health agreement, established in 1952, that aims to protect cultivated and wild plants by preventing the introduction and spread of pests and diseases. It is aimed at securing a common and effective action to prevent the spread and introduction of pests and diseases of plants and plant products, and to promote appropriate measures for their control. The IPPC extends beyond the protection of cultivated plants to the protection of natural flora and plant products. It takes into consideration both direct and indirect damage by pests and diseases, so it includes weeds. It also covers vehicles, aircraft and vessels, containers, storage places, soil and other objects or material that are potential carriers of pests and diseases. The IPPC provides a framework and a forum for international cooperation, harmonization and technical exchange between contracting parties. Its implementation involves collaboration by National Plant Protection Organizations, the official body that must be established by governments to conduct the functions specified by the IPPC and Regional Plant Protection Organizations (RPPOs), which can act as coordinating bodies at a regional level to achieve the objectives of the IPPC.

Although the IPPC uses the term pest to define both invertebrates and pathogens for greater clarity this article refers to both pests (invertebrates and nematodes) and diseases (caused by pathogens).

Human Biosecurity

The WHO is the directing and coordinating authority for health within the United Nations system. It is responsible for providing leadership on global health matters, shaping the health research agenda, setting norms and standards, articulating evidence-based policy options, providing technical support to countries, and monitoring and assessing health trends (www.who.int). Through WHO, governments can jointly tackle global health problems and improve people's well-being. Increasingly the OIE and WHO are working together toward a 'One Health' concept, due to the strong link between animal and human diseases. Together the OIE, WHO, and FAO have created the Global Early Warning System, a platform shared by the three organizations to improve early warning on animal diseases and zoonoses (those diseases that are naturally transmitted between vertebrate animals and humans) worldwide.

The Sanitary and Phytosanitary Agreement

The SPS Agreement came into force with the establishment of the WTO on 1 January 1995 and concerns the application of food safety and animal and plant health regulations. The basic aim of the SPS Agreement is to maintain the sovereign right of any government to provide the level of health protection it deems appropriate, but to ensure that these sovereign rights are not misused for protectionist purposes and do not result in unnecessary barriers to international trade. It allows countries to set their own standards on SPS measures (i.e., measures to maintain animal and plant health and biosecurity), but such measures must be based on science. They should be applied only to the extent necessary to protect human, animal, or plant life or health and they should not arbitrarily or unjustifiably discriminate between countries where identical or similar conditions prevail.

All countries maintain measures to ensure that food is safe for consumers, and to prevent the spread of pests and diseases among people, animals and plants. Member countries (signatories to the SPS Agreement) are encouraged to use international standards, guidelines, and recommendations where they exist. However, members may also use measures that result in higher standards if there is scientific justification. These SPS measures can take many forms, such as requiring products to come from a pest and disease-free area, inspection of products, specific treatment or processing of products, setting of allowable maximum levels of pesticide residues, or permitted use of only certain additives in food. Sanitary (human and animal health) and phytosanitary (plant health) measures apply to domestically produced food or local animal

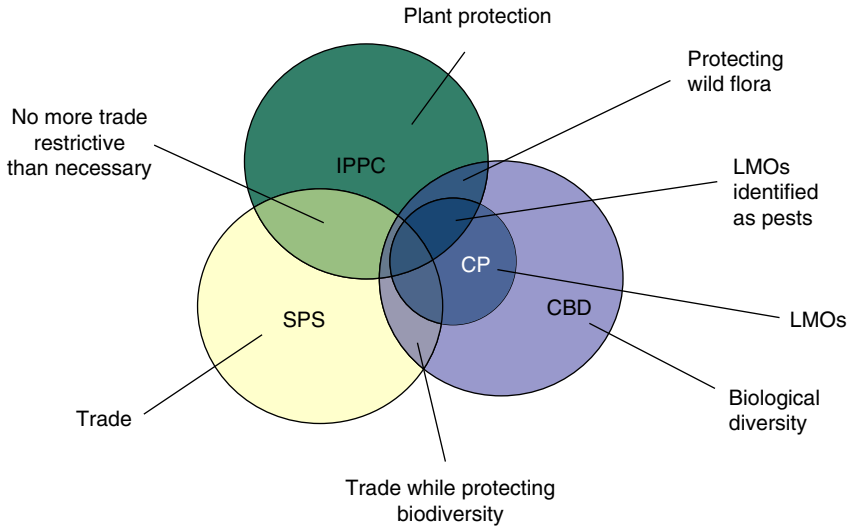

Figure 1 The international regulatory framework for plant biosecurity, comprising the International Plant Protection Convention (IPPC), the Sanitary and Phytosanitary (SPS) Agreement, the Convention on Biological Diversity (CBD), and the Cartagena Protocol (CP). LMO is defined as living modified organism. The main area of governance of each is indicated by a solid line, and the intention of each is indicated by a dotted line (http://www.phytosanitary.info/sites/phytosanitary.info/files/1198163278743_Day_1_A_Welcome_and_IPPC_lecture2_1.ppt).

diseases and plant pests and diseases, as well as to products coming from other countries.

The Convention on Biological Diversity

The CBD is a global, comprehensive agreement addressing all aspects of biological diversity, genetic resources, species, and ecosystems. On 29 January 2000, the Conference of the Parties to the CBD adopted a supplementary agreement to the Convention known as the Cartagena Protocol (CP) on Biosafety. The protocol seeks to protect biological diversity from the potential risks posed by living modified organisms resulting from modern biotechnology. It establishes a procedure for ensuring that countries are provided with the information necessary to make informed decisions before agreeing to the import of such organisms into their territory. In 2005, the Secretariats of the IPPC and the CBD signed a Memorandum of Cooperation to promote cooperation and avoid unnecessary duplication in the field of plant biosecurity. The joint work program between the two Secretariats includes regular consultations to provide input on one another's activities. The relationship between the IPPC, CBD, and CP is indicated in Figure 1.

National and Regional Biosecurity Frameworks

International conventions and agreements are generally signed with national level governments, but how this then impacts on subnational governments is dependent on domestic arrangements. In Australia, for example, the states operate their own biosecurity system within a national framework, while some activities (e.g., national border security) remain a national responsibility. National governments have signatory obligations under international agreements and conventions such as the IPPC.

The role of subnational groups, including semiautonomous government bodies, formal industry groups, informal alliances or individuals, all play a role in biosecurity, directly or indirectly. The role of subnational governments (e.g., state and provincial governments) in biosecurity may vary from nation to nation. It is important to remember that stakeholders below the national level play a role in influencing national policy, which in turn influences international policy.

Regional groups also play a significant role in biosecurity. Under the IPPC, RPPO work on plant biosecurity at a regional level. At present there are 10 RPPO:

- Asia and Pacific Plant Protection Commission (APPPC)
- Comunidad Andina
- Comite de Sanidad Vegetal del Cono Sur
- Caribbean Plant Protection Commission
- European and Mediterranean Plant Protection Organization
- Inter-African Phytosanitary Council
- Near East Plant Protection Organization
- North American Plant Protection Organization
- Organismo Internacional Regional de Sanidad Agropecuaria
- Pacific Plant Protection Organization (PPPO)

Case Study – the Australian Biosecurity Framework

Australia is a party to the WTO and belongs to two RPPO – the APPPC and the PPPO. It cooperates with both RPPOs to develop regional standards for phytosanitary measures. The Australian biosecurity system encompasses the full range of activities undertaken by governments, industry, natural resource managers, custodians or users, and the community across the biosecurity continuum, including prevention, emergency preparedness, detection, response, recovery, and ongoing management of pests and diseases.

The federal (Commonwealth) government has formal responsibility for international government-to-government

relations and Australia's compliance with international obligations under the SPS Agreement, the IPPC, and the CBD. In 2013, the main federal government department that is responsible for biosecurity for plants, animals (including aquatic animals), and marine life is the Department of Agriculture, Fisheries and Forestry (DAFF), which oversees the Quarantine Act 1908. DAFF has primary responsibility for managing Australia's biosecurity system. Environmental biosecurity is covered partly by the Department of Sustainability, Environment, Water, Population, and Communities, which administers the Environment Protection and Biodiversity Conservation Act 1999.

Beneath the Federal government, every state and territory of Australia has its own government, and each of these has additional legislation regarding biosecurity. In Western Australia, for example, the Biosecurity and Agricultural Management Act 2007 is the main legislation. Within a state or territory there may also be regional regulations that apply to certain areas or regions. However, at all levels of government, compliance with international obligations must still occur. Generally, this compliance is contained with the federal and/or state legislation. Therefore, if a company wants to export a product from a particular state of Australia to another country, the company must negotiate with that country through DAFF and demonstrate compliance with all relevant legislation applicable for Australia and the importing country.

The federal, state and territory governments (with exception of Tasmania) signed an Intergovernmental Agreement on Biosecurity in January 2012 to enhance Australia's biosecurity system and strengthen the collaborative approach between the federal and state and territory governments (IGAB, 2012). The intergovernmental agreement recognizes that biosecurity is a shared responsibility and sets out the principles that underpin the operation of a national biosecurity system; describes the key components and features for the national biosecurity system, primarily for animal and plant pests and diseases in both aquatic and terrestrial environments, including pest animals, weeds, and zoonotic diseases; describes steps to strengthen the working partnerships and to enable biosecurity measures to be implemented consistently and efficiently across the biosecurity continuum; establishes nationally agreed approaches to prevent, prepare for, detect and mitigate biosecurity risks, and respond to, manage and recover from biosecurity incidents should they occur; and identifies national priorities to strengthen the national biosecurity system and sets out a process for identifying and reviewing priorities.

The goal of the Australian biosecurity system is to minimize the impact of pests and diseases on Australia's economy, environment, and the community, with resources targeted to manage risk effectively across the biosecurity continuum, while facilitating trade and the movement of animals, plants, people, goods, vectors and vessels to, from, and within Australia. The objectives of the national biosecurity system are to provide arrangements, structures and frameworks that:

- Reduce the likelihood of exotic pests and diseases, which have the potential to cause significant harm to the economy, the environment, and the community (including people, animals, and plants), from entering, becoming established or spreading in Australia;
- Prepare and allow for effective responses to, and management of, exotic and emerging pests and diseases that enter, establish or spread in Australia; and
- Ensure that, where appropriate, significant pests and diseases already in Australia are contained, suppressed or otherwise managed.

The Biosecurity Continuum

The changing global environment means there is a need for a greater emphasis on managing the whole biosecurity continuum, onshore, at the border and offshore, rather than focusing primarily on interventions at the border. Effective biosecurity management requires activities offshore to reduce risks reaching the border, and actions onshore to deal with incursions.

With an increasing biosecurity risk scenario, an effective biosecurity continuum is needed to facilitate safe movement of goods and people and maintain the health status of human, animal and plants and the environment in general. It provides the necessary regulatory framework that governs trade within and between countries. The biosecurity continuum reduces the probabilities of incursions of harmful organisms and increases the probability of successful eradication of pest and disease incursions. Biosecurity policies and regulations across the continuum help to maintain existing markets and create new and improved trade opportunities. Communication, education and awareness of quarantine issues are integral parts of the biosecurity continuum (EPPRD, 2013).

In the past, border quarantine was the mainstay of protection from exotic pests and diseases; however the enhanced risk of invasion by biosecurity threats has necessitated the need for implementation of a continuum of biosecurity approach to manage pest and disease risks where they can be most effectively managed. The biosecurity continuum approach comprises a coordinated system of pest risk analysis, inspection, surveillance and control using risk mitigation measures preborder, border, and postborder to prevent the entry, establishment, and spread of harmful organisms.

Preborder Biosecurity

Preborder biosecurity risk management includes the use of international agreements such as the SPS Agreement or the IPPC for the imposition of import standards, preborder checks and treatments of goods to be imported, as well as information-sharing and international networking between research and development and biosecurity agencies.

Preborder activities seek to prevent biosecurity risks reaching borders of a country or region. Threat identification and risk assessment are significant components of preborder risk management. The preclearance of passengers or goods in their country of origin is consistent with the principle of managing biosecurity risks preborder. Offshore preclearance as part of the preborder biosecurity is gradually expanding; for

example, it may include overseas fumigation certification for full containers and preclearance of some fruits and thus maintaining the quarantine pest risk offshore. The risk mitigation measures are implemented consistent with the obligations under the SPS Agreement and the basic obligations are that biosecurity risk mitigation measures must:

- Be applied only to the extent necessary to protect life or health and not be more trade restrictive than required;
- Be based on scientific principles and not maintained without sufficient scientific evidence; and
- Not constitute arbitrary or unjustifiable treatment or a disguised restriction on trade.

The SPS Agreement encourages WTO member countries to harmonize their measures by developing their biosecurity risk mitigation measures on agreed international standards. Where relevant international standards do not exist, the member country must base its measures on proper scientific assessment of the risks.

Border Biosecurity

Border biosecurity risk management includes checks by the border quarantine authorities of incoming goods and passengers that have potential to be pathways for pest and disease introduction. Declarations of risky items by passengers, mail screening for biological material, and postentry quarantine screening for high-impact pests and diseases are some of the key activities of border biosecurity risk management programs. Border biosecurity primarily aims to minimize the likelihood of entry of biosecurity threats through operation of effective quarantine inspection measures consistent with international obligations. It facilitates the safe international and interstate or regional movement of goods, people and trade in biosecurity risk material through the provision of inspection and certification services. The border biosecurity involves the following activities:

- Screening of all imported material for quarantine pests and diseases;
- Examination of material on arrival;
- Examination of health certification accompanying consignments for compliance with import permit conditions;
- Managing the risk associated with variations of the import permit conditions to ensure equivalence; and
- Liaising with overseas certifying authorities to ensure the certification is consistent with the permit conditions.

Postborder Biosecurity

Postborder biosecurity risk management includes the use of subnational (state and regional) boundaries to monitor and restrict the movement of biosecurity risk materials, surveillance, and monitoring activities for pests and diseases and incursion response planning. Monitoring and surveillance for pest and disease incursions, pest and disease spread and establishment in new regions are some of the key activities of postborder biosecurity program. Pest surveillance information is vital to claim pest and disease freedom status of a region or country. The postborder surveillance is necessary to demonstrate area freedom in order to meet trading partner requirements, as well as to demonstrate successful pest or disease eradication at the end of an eradication response. Pest and disease surveillance programs include targeted active surveillance, generally undertaken by specialists, while passive surveillance often engages growers and general community in reporting any suspect pest or disease to the biosecurity institutions. The efficiency of passive surveillance depends on growers and general public awareness and interest in reporting any unusual sightings of pests and diseases and their symptoms.

Active pest surveillance involves deliberate, coordinated searching, diagnosis, and reporting of pests and diseases. Passive pest surveillance includes observations by growers or investigations of pest or disease occurrences by private consultants or agricultural specialists. Growing volumes of tourism and trade are putting pressure on the biosecurity system and, while interventions at the preborder and border prevent many pests and diseases from entering a country, a well developed surveillance program is necessary to detect the pests and diseases that manage to get in. The postborder surveillance activity aims to minimize the risk of establishment of exotic pests and diseases by implementing early pest or disease detection strategies. Early detection of pest or disease incursion is crucial for successful incursion management. The postborder biosecurity programs keep a 'vigilant eye' on any new biological threat and develop appropriate strategies to eradicate pest and disease incursions.

Postborder biosecurity programs develop best-practice procedures and contingency plans to deal with incursions of exotic pests and diseases for eradication, containment or appropriate control. The approach involves preparation of biosecurity plans for each industry, including farm biosecurity plans where appropriate. The industry biosecurity plans pro-actively identify the key threats to productivity, sustainability and marketability, and outline preventive and response strategies. Each industry biosecurity plan summarizes surveillance and monitoring for the high-risk threats, incident response in the event of a pest or disease incursion, containment, eradication and other management measures, research and development priorities, and biosecurity communication and training needs.

The postborder biosecurity includes farm biosecurity measures for maintaining farm hygiene to prevent introduction of biosecurity threats to plants and animals into the farm from anywhere. Fodder, seed, stock, machinery, vehicles, and people can carry weed seeds, pest eggs, or pathogen spores as well as contaminated soil. Accessing clean material from known pest-free sources minimizes pest and disease risk. Farm biosecurity aims to keep land, crops, and stock free of pests and diseases by managing the movements of stock, produce, and equipment most likely to carry pests and diseases. Farm biosecurity measures minimize the entry and spread of pests and diseases and these measures include:

- Put up a sign to inform farm visitors that all machinery, vehicles, bins and boxes coming onto the farm property must be clean to reduce the potential of any pest or disease introduction;

- Advise visitors that their vehicles, boots and hand tools must be clean of potential pests and diseases;
- Restrict the use of visiting vehicles, using your vehicle to carry visitors around the farm where possible;
- Check the cleanliness and quality of any seed or grain before it comes to the farm. Use pest-and disease-free certified or accredited stock, seed and planting material;
- Ensure that agricultural machinery and equipment are cleaned of plant material and most soil before being moved to a new work site;
- Consider washing footwear and hand equipment before entering and leaving high-risk sites when working in nurseries, animal houses, stockyards and seed crop areas; and
- Identify pest and disease infested/infected areas, if any, on a farm and avoid pest and disease spread to clean areas.

Introduction of an exotic pest or disease may pose a threat to a country's agriculture, economy, environment, and trade. Therefore, the primary goal when a new pest or disease is detected is to eradicate it. Successful eradication relies on preparedness and implementation of appropriate response plan for eradication.

Core Biological Disciplines

The core disciplines that underpin biosecurity are pathology (fungi, oomycetes, bacteria, viruses, nematodes, viroids, and phytoplasmas), parasitology/entomology (insects as well as mites and snails), and weed science. Within each of the key science disciplines biosecurity is reliant on many different specialists. Ebbels (2003) further described that as a branch of applied biology, with an endless variety of problems and circumstances that have to be dealt with, quarantine can involve almost any branch of science. Beale *et al.* (2008) stated that biosecurity requires knowledge to exclude, eradicate, or effectively manage the biological threats to the economy, environment, or community. The combination of science disciplines provides the knowledge to understand the potential impact of these pests and diseases on an organism and its ecosystem. Biosecurity should be considered a melding of many scientific disciplines and not a discipline on its own merit.

Science disciplines contribute to providing knowledge of the pest biology. This includes determining the risk posed for the introduction of a pest or disease and the capacity for it to establish in a new environment. Once established, will the pest or disease spread and what will be the social, economic, and environmental impact? The science disciplines provide advice to decision makers on the application of risk mitigation measures such as containment, eradication, or exclusion. The specific pest or disease information enables decision makers to achieve the desired outcome from a biosecurity response utilizing the most appropriate actions. However, by its nature there are often information gaps and decisions must be made on the best judgment/advice of the discipline experts and may lead to the initiation of research activities to fill the information gaps (Susan Worne, personal communication).

Diagnosis of the Pest

Diagnostics is the core of any countries biosecurity system. Countries that do not have this capability cannot satisfy the requisite international agreements for trade and are unable to protect against the introduction of exotic pests and diseases (Kong *et al.*, 2012). The accurate, repeatable, and often rapid diagnosis of pests and diseases of concern is critical when inspecting a product entering a country, products leaving the country as trade or assessing the presence or absence of a pest or disease. Diagnosis needs to utilize numerous tools from traditional (morphology) taxonomy through to the latest molecular and digital methods. Although there is a growing reliance on molecular methods for diagnosis of pests and diseases, taxonomy based on the morphology of the organism must always to be available and for some disciplines it is in danger of disappearing (Crous, 2005).

Kong *et al.* (2012) confirmed this position by stating that the loss of taxonomic expertise is a global trend and comes at a time when, because of WTO and SPS regulations, there is greater emphasis on high-level pest and disease identification. New molecular and digital tools are assisting in addressing the growing shortage of specific expertise but there are limitations. Deoxyribonucleic acid barcoding is one such tool but its role is still dependent on the support of traditional taxonomists (Kipling *et al.*, 2005). Digital tools provide the opportunity to remove all but the final definitive identifications from taxonomists (Kong *et al.*, 2012). As identified by Guest (2009), there is a continuing decline in investment in key taxonomic positions in plant protection disciplines such as plant pathology and nematology in developed countries and trends indicate this situation is unlikely to improve. A biosecurity system that utilizes various new tools, such as molecular or digital, and is more strategic about its use of key traditional taxonomic expertise will be the most successful in the future.

The use of new tools does present some perils in a biosecurity context. For example, under the IPPC, biosecurity/quarantine decisions are made based on the diagnosis of an organism (ISPM 1). This is in contrast to the animal sector where decisions are made based on the presence/absence of a disease. This presents a challenge for plant pathology as the availability of new tools is resulting in identification of many new organisms for which there is no ascribed disease. For example, the number of named plant viruses has increased from 380 to over 1000 since 1991 (Rodoni, personal communication). If decisions are made by trading countries to decline access of product based simply on the presence of an organism and not symptomatology, then unnecessary significant losses may be incurred. The same scenario exists when eradication operations are undertaken. Valuable plant material may be destroyed because of the presence of an organism even though no symptoms of a discernible disease are present. International policy governed through the IPPC will need to address this issue in the near future and consider the redefining from organism to disease with identifiable symptoms (McKirdy *et al.*, 2012).

Ecology and Epidemiology

Once an exotic pest or disease has been identified in a new area, decision makers need to initiate control or eradication activities. Ecology and epidemiology are critical skills in developing appropriate contingency plans and putting these

plans into action should a detection be made. Surveillance activities are utilized to confirm pest or disease area freedom and to assist in delimiting the area infested by an exotic organism. Ecological and epidemiological skills are necessary when developing a survey plan. Epidemiologists within the disciplines of plant pathology and entomology assist decision makers through their knowledge of the behavior of organisms in the field. Epidemiology has been described in detail by Madden *et al.* (2007) and Berryman (1978).

Defining the genetic relationships between strains/biotypes, describing how a pest or disease is able to survive and spread within an ecosystem, identifying the pathogenicity/vigor/fitness and providing knowledge to enable commencement of appropriate quarantine, eradication and management plans are the role of scientists with expertise in ecology or epidemiology.

Modeling

Skilled modelers play an important role in assisting ecologists/epidemiologists in providing advice. Numerous models have been developed/utilized to assist decision makers in determining the best options when addressing the detection of an exotic pest or disease or in planning for the potential introduction of a pest or disease. Modeling should be considered a tool that can assist rather than provide the definitive system on which decisions are based. Biosecurity provides significant challenges for modeling in that there are often large gaps in available knowledge and there is not the capacity to ground-truth. If dealing with a local pest or disease, modelers working with pest biologists can commission research to address key information gaps or to ground-truth the outputs of a model. By its very definition, biosecurity is dealing with pests or diseases that are not present so there is no capacity to ground-truth outputs. The data available on specific pests or diseases are in most cases gained from areas where the pest or disease is endemic. Researching an endemic pest or disease does not necessarily raise the same questions that arise when decision makers are considering the introduction, establishment and spread of a pest or disease into a new area.

Statistics

Barrett *et al.* (2010) described the role that statistics can play in designing an appropriate surveillance strategy when addressing plant biosecurity threats. Statistical modeling can assist in the detection of pests or diseases while addressing the challenges of multiple data sources, stratifying for differential risk, managing costs, and providing the required power of detection (Barrett *et al.*, 2010). This modeling can also assist in determining the resources to be utilized for detection while meeting the resource constraints.

Economics

Economics is an essential part of any decision-making process in biosecurity. Economists play an important role in determining the potential impact of a pest or disease introduction, prioritizing and managing risks, assessing the merits of eradication versus containment versus management, assessing appropriate compensation for affected stakeholders following a biosecurity incident and estimating the social welfare effects of market access issues or new pest or disease introductions (Liu *et al.*, 2011; Carrasco *et al.*, 2012; Mumford, 2011).

Bioinformatics/informatics

A growing challenge for biosecurity is the storing, maintenance, accessibility, and the usability of data. A country's biosecurity position is dependent on it being able to provide evidence of the status of pests and diseases of concern. This status is critical for both setting restrictions on the importation of product and in gaining market access. The capacity for all stakeholders to gather data on the status of pests and diseases is growing at ever increasing rates as technologies, such as application of the various *–omics*, for their detection continually improve (Alkan *et al.*, 2011). However, the storage of these data are presenting biosecurity systems with the challenge of being able to store the data with the capacity to retrieve and use the data as required. Bioinformatics/informatics applies information technologies to allied fields such as biosecurity. Bellgard and Bellgard (2011) stated that bioinformatics starts at the farm gate and extends through the 'chain of custody' and the challenge is to embrace bioinformatics to ensure biosecurity endeavors can deliver food security.

Social Science

Biosecurity can be a costly and complex issue and, for it to be successful, it requires the shared responsibility of all stakeholders. The stakeholders include government, industry, and the general community (Beale *et al.*, 2008). Social scientists play an important role in achieving the engagement of all sectors of community. Community engagement has been described as a continuum of participation from passive receipt of information, consultation, involvement, partnership through to self-empowered communities that independently initiate actions (Kruger, 2011).

Social science also plays an important role in addressing biosecurity effectively across international borders. Falk and Wallace (2011) stated that the geographic divide between countries introduces both politicoeconomic and sociocultural differences. No one of these aspects, political, economic, social or cultural, is more significant than the other in terms of managing biosecurity effectively (Falk and Wallace, 2011). Social science has a critical role to play in the effective operation of any biosecurity system.

Risk Assessment and Management

Prevention

It prevents the introduction of exotic pest or disease into a region. This strategy focuses on blocking the potential pathways for pest or disease entry. The prevention strategies destroy the pest or disease population before it arrives or establishes in a new area (Gamliel and Fletcher, 2005).

Containment

The containment strategies are implemented after a pest or disease has been introduced in a new area with the objective to prevent and restrict its further spread by reducing the pest or disease population and activities to prevent new infestations and spread (Gamliel and Fletcher, 2005).

Eradication

The eradication strategies are aimed at destroying the pest or disease incursion from the invaded area. It involves elimination of all the existing pest or disease populations from all infested sites, hosts within the area and buffer zone (Gamliel and Fletcher, 2005).

Management

The management strategies are implemented when the pest or disease incursion has established and spread. The aim of management strategies is to minimize the economic and environment impact of pest or disease (Gamliel and Fletcher, 2005).

Communication

Biosecurity communication plans identify relevant stakeholders, internal as well as external, develop key messages, engage with stakeholder groups and monitor the effectiveness of communication. Stakeholder interests and responsibilities may be significantly affected by regulatory risk-management decisions and consultation with external stakeholders throughout the risk-management process is needed. Biosecurity risk communication activities involve a number of mechanisms to inform and update stakeholders via scheduled meetings with stakeholder representatives, and publication of relevant information in stakeholders' journals and periodicals. Successful risk communication requires expertise in conveying understandable and usable information to both internal and external stakeholders.

A key driver for any research in biosecurity is the effective delivery and adoption of research outputs. Scientists can apply their innovation to key challenges and deliver outputs that have the potential to significantly change the mode of operation. However, as biosecurity is very tightly regulated by both national and international regulations, the rate of adoption is often very slow. Regulators need to have a high level of confidence that the implementation of any new research output will still enable all regulatory requirements to be met and, as such, are very conservative. Scientists often find it hard to accept the slow rate of adoption of new research as it is clear to them that a new output will greatly improve the operations of biosecurity. The adoption phase of any research output often involves mundane steps that result in loss of interest for researchers who are continually seeking new innovation. The introduction of social scientists to improve the communication between the innovators (researchers) and the conservative regulators and to develop processes to enable the gradual adoption of research outputs is needed. This will enable the researchers to continue being innovators and focused on the needs of the regulators, without losing interest in a topic as the tasks become more mundane as well as convincing the regulators that new outputs will benefit the operations they undertake in order to meet regulatory requirements.

The disciplines and skills discussed above are not a definitive list of those used in biosecurity. As new challenges are identified in ensuring that a country maintains and adheres to its biosecurity status, there will be a continuing need to seek input from other disciplines of science as well as, for example, engineering, geographic information system, and educators.

Concluding Remarks

Biosecurity is a relatively new concept and its meaning and scope is still evolving. It is emerging as one of the most important issues facing the global community, for a number of reasons (Cock, 2003):

1. Producers' livelihoods can be destroyed by pests and diseases of animals and plants.
2. Processors rely both on high-quality primary produce and on stable consumer demand, based on trust in their products. They are at severe economic risk if either is compromised, either through an external failure of biosecurity measures, or through internal risks, such as contamination in the course of processing.
3. Ecosystem stability, and hence maintenance of ecosystem services to the environment and society, can be threatened by unwanted changes resulting from the introduction of invasive alien species or genotypes.

There is a growing need for countries to establish biosecurity systems to safeguard their resources from new and exotic biological threats. Two main factors have increased the risk of biosecurity threats, namely, the increased global movement of biological materials and the rapid development of technologies associated with genetic modification (Cock, 2003).

Biosecurity safeguards agriculture, the economy, the environment, and human health from the risks of introduced pests, diseases and weeds. As well as preventing new animal and plant pests, diseases and weeds from arriving, biosecurity involves controlling those already present.

The plant sector, the source of food and feed worldwide, is facing an increasing number of pest and disease outbreaks that can significantly affect food production and availability and adversely impact natural biodiversity. A significant proportion of food that can feed well over 1 billion people is being lost to pests and diseases every year.

Pests and diseases are causing significant production and postharvest food losses worldwide, particularly in many food-insecure developing countries. The increase in detection and spread of threatening pests and diseases to new areas has revealed the need for a commitment and shared responsibility for global biosecurity to limit pest and disease impacts.

The outbreak of the Ug99 strain of the stem rust pathogen of wheat in Uganda, to which the world's major wheat varieties have no resistance, is alarming. This strain is apparently spreading in Uganda, Kenya, Ethiopia, Sudan, Yemen, and Iran and has potential to cause significant impact on global wheat yields and thus on food security. The total world area planted to wheat is well over 200 million hectares. Wheat varieties resistant to Ug99 may exist but there is not enough

seed available to plant in millions of hectares even in areas in eastern Africa, the near East and central and south Asia that are at are at high risk of exposure to this strain.

The threat posed by Ug99 to global food security is aptly captured on blog.

> *…So even with a best case scenario, in which there is ample money and cooperation from all parties involved, it would take years to obtain enough Ug99 resistant wheat seed for only a small portion of the wheat fields of the world. In the meantime, the wheat harvest could be devastated. Wheat provides about 20% of the world's total agricultural production, in terms of caloric content of the food. It is one of the top staple crops. (The others are: maize, rice, soy, and barley.) If the wheat crop is devastated, then every other food will be in higher demand. Food prices would rise across the board. The world is so heavily dependent on just a few major staple crops, that any major widespread problem with just one of those crops will cause worldwide problems with agriculture and food.…*

This situation would be disastrous if one more staple food crop in the near future is threatened by Ug99-like virulent strain.

Development and implementation of a global biosecurity strategy has become a necessity to minimize the exposure of global food security system, natural biodiversity, lifestyle and human health and well-being to biosecurity threats.

Glossary

Abiotic stress Outside (nonliving) factors that can cause harmful effects to plants, such as soil conditions, drought, flooding, and extreme temperatures.

Bacillus thuringiensis A naturally occurring microorganism that produces a toxin protein that only kills organisms with alkalineing stomachs, namely such as insect larvae. As and when delivered as a part of the whole killed organism, this toxin protein has been used for biological control for decades. The genetic information that encodes the toxin protein was identified and moved into plants to make them insect tolerant.

Biotechnology Development of products by a biological process. Production may be carried out by using intact organisms, such as yeasts and bacteria, or by using natural substances (e.g., enzymes) from organisms.

Biotic stress Living organisms that can harm plants, such as viruses, fungi, bacteria, and harmful insects. See Abiotic stress.

Composition analysis The determination of the concentration of compounds in a plant. Compounds that are commonly quantified are proteins, fats, carbohydrates, minerals, vitamins, amino acids, fatty acids, and antinutrients.

Conventional breeding Breeding of plants carried out by controlled transfer of pollen from one plant to another followed by selection of progeny through multiple generations for a desirable phenotype. This method has also often included irradiation or mutation of plants or seeds to induce extra variation in the donor material.

Genetic engineering A technology used to alter the genetic material of living cells in order to make them capable of producing new substances or performing new functions, or to increase, decrease, or eliminate an existing substance or function.

Genetically modified organisms A genetically modified organism is an organism whose genetic material has been altered using genetic engineering techniques.

Risk A function of the probability of an adverse health effect and the severity of that effect, consequential to a hazard(s).

Risk management The process, distinct from risk assessment, of weighing policy alternatives, in consultation with all interested parties, considering risk assessment and other factors relevant for the health protection of population and for the promotion of fair practices, and if needed, selecting appropriate prevention and control options.

RNAi RNA interference (RNAi) is a phenomenon whereby small double-stranded RNA (referred as small interference RNA or siRNA) can induce efficient sequence-specific silencing of gene expression.

Substantial equivalence In the report of the 1996 FAO/WHO Expert Consultation, substantial equivalence was identified as being "established by a demonstration that the characteristics assessed for the genetically modified organism, or the specific food product derived therefrom, are equivalent to the same characteristics of the conventional comparator. The levels and variation for characteristics in the genetically modified organism must be within the natural range of variation for those characteristics considered in the comparator and be based upon an appropriate analysis of data." In the Codex Guideline for the Conduct of Food Safety Assessment of Foods Derived from Recombinant-DNA Plants (2003), the concept of substantial equivalence is described as "a key step in the safety assessment process. However, it is not a safety assessment in itself; rather it represents the starting point which is used to structure the safety assessment of a new food relative to its conventional counterpart. This concept is used to identify similarities and differences between the new food and its conventional counterpart. It aids in the identification of potential safety and nutritional issues and is considered the most appropriate strategy to date for safety assessment of foods derived from recombinant-DNA plants. The safety assessment carried out in this way does not imply absolute safety of the new product; rather, it focuses on assessing the safety of any identified differences so that the safety of the new product can be considered relative to its conventional counterpart."

Introduction

There is nothing new about introducing novel traits into plants and animals just the methods used to do this have evolved over time. Agriculturalists have been genetically modifying crop plants through crossbreeding, mutation selection, and culling those with undesirable characteristics for hundreds of years. Thus, from a scientific perspective the term 'genetically modified (GM) organism' is not an accurate descriptor of the products produced solely of modern biotechnology, as virtually all domesticated crops and animals have been subjected to varying degrees of genetic modification. On balance, neither the weight of scientific research nor the great majority of the scientific community support the view that organisms modified using the present-day biotechnology pose novel or greater dangers to the environment or human health than organisms developed by other means. Ironically, many of the daily staples would be banned if subjected to the rigorous standards to which biotech crops are subjected. Potatoes and tomatoes contain glycoalkaloids, and if one were to follow labeling to its logical conclusion, one should display a warning label that may contain genes from deadly nightshade. Indeed, biotechnology approaches can be employed to downregulate or even eliminate the genes involved in the metabolic pathways for the production and activation of such plant toxins and also allergens, such as globulins in peanuts.

Over time, and especially during the past century, plant and animal breeders expanded the tools of genetic manipulation beyond conventional crossbreeding to use a variety of other breeding techniques. In the case of plants, these tools include aneuploidy, polyploidy, embryo rescue, protoplast fusion, somaclonal variation, anther culture, colchicine for chromosome doubling, and mutation breeding through either radiation or chemicals. Examples of crops subjected to these breeding techniques include bananas and watermelons (aneuploidy, 3X chromosomes); bread wheat (allopolyploidy, 6X chromosomes from three different species, an old event); broccoflowers (embryo rescue); male sterility in cauliflower (radish cauliflower protoplast fusion); barley (anther culture to speed up development of improved varieties) and asparagus (colchicine chromosome doubling for 'super males'); tomatoes (wide crosses with high toxin glycoalkaloid relatives); and Asian pears, grapefruits, and pasta wheat (irradiation breeding for fungal resistance in the former and modified gluten proteins in the latter). These techniques do not allow any control at the genome level; rather, multiple genes are transferred together or mutated and unwanted traits are eliminated through subsequent selection and backcrossing. Plants created by these conventional phenotypic selection techniques undergo no formal food or environmental safety evaluation before introduction into the environment and marketplace, other than normal agricultural variety testing. Despite the extensive genetic manipulation of crop plants by these diverse methods, cases of novel or completely unexpected adverse consequences for commercialized varieties of these crops are extremely rare. At the deoxyribonucleic acid (DNA) level, the massive accumulation of sequencing data shows extensive genetic similarity among genomes of diverse organisms that are only remotely related. For example, parts of the nucleic acid sequence of a common bacterium present in our guts, *Escherichia coli*, have been found in the DNA of organisms such as oilseed rape, amphibians, birds, grasses, and mammals, including humans. Such findings put in doubt the value of assigning genes to a particular species and the validity of using terms such as 'species-specific' DNA.

Thus, risk assessment should have this fact as a basis and be undertaken within a regulatory framework that ensures adequate protection of the consumer and the environment while not stymieing innovation. Science-based risk assessment identifies potential hazards, quantifies the probabilities of occurrence of those hazards, and accounts for uncertainty with significant safety thresholds – typically set at 1000 times the likely level of a risk to occur. The data that are currently used for the safety assessment of GM crops have focused on the potential perceived risks associated with modern biotechnology. There are now worldwide data from more than 17 years of commercial use of GM crops and almost three decades of research experience and no verified adverse consequences have been reported. These results have allayed the fears of many and have for the most part resulted in the greater acceptance of GM foods. Indeed, many scientists question the painstaking premarket safety assessment of GM crops as practiced in some countries and recommend that the extent and type of data that is part of a current safety assessment be updated to reflect this long-term safe experience with GM crops coupled with new information about plant genome plasticity (Bradford *et al.*, 2005a,b; Kalaitzandonakes *et al.*, 2007; McHughen, 2007; McHughen and Smyth, 2008). They suggest that refinements to the process could include incorporation of factors, such as 'familiarity' (e.g., for commonly used proteins, such as CP4 EPSPS, Cry1Ab, and PAT) and the source of the gene (e.g., when the gene is from the same crop species or is one with a history of safe use), into the overall safety assessment, influencing the extent to which event-specific data are needed. This is considered to be a sensible and pragmatic approach to regulatory oversight.

Despite clear asymmetry and lack of consensus in regulatory systems worldwide and in many instances almost insurmountable challenges, by 2012 GM crops were grown commercially on 175 million hectares, which is 15 million hectares more than that in 2011 with a 9% growth since then. There was a 100-fold increase in hectarage from 1.7 million hectares in 1996 to 175 million hectares in 2012, making biotech crops the fastest adopted crop technology in the history of modern agriculture (James, 2013). Developing countries grew more than 50% of global biotech crops in 2012 and for the first time exceeded industrial countries hectarage. Of the 28 countries planting biotech crops in 2012, it is noteworthy that 19 were less developed countries. Of the 17.3 million farmers, who grew biotech crops, more than 90%, or 16 million, were small resource-poor farmers in developing countries. In addition, biosafety regulations are in place in 57 countries. Although North America still leads in research, more than half of the 63 countries engaged in biotech research, development, and production are developing countries. Adoption is further expanded on in another part of this encyclopedia.

The vast majority of biotech products approved to date are in the area of agronomic traits, especially the area of pest control but with an increasing interest in abiotic stress tolerance, which is gaining prominence as external pressures from climate

change to land-use change. The coming generations of crop plants can be grouped into four broad areas each presenting what, on the surface, may appear as unique challenges to regulatory oversight. The present and future focus is on continuing improvement of agronomic traits, such as yield and abiotic stress, in addition to the biotic stress tolerance of the present generation; crop plants as biomass feedstocks for biofuels and 'biosynthetics'; value-added output traits, such as improved nutrition and food functionality; and plants as production factories. Animals will also enter the regulatory net and although they may parallel plants at some level of application, namely disease resistance, yield, food quality, and as pharming factories, they have clear departures on many significant levels. The issues of ensuring biosafety for the consumer and the environment are of prime concern, irrespective of whether the organism is a microbe, plant, arthropod, or animal. All organisms continuing improvements in molecular and genomic technologies are contributing to the acceleration of product development. One of the subtler modification systems that will provide a challenge for regulatory oversight is, what may be referred to as, next generation directed mutagenesis. Genome editing, specifically genome editing with engineered nucleases, is a form of fine-tuned gene modification using novel nucleases (such as zinc finger nucleases, transcription activator-like effector nucleases, and clustered regularly interspaced short palindromic repeats) that results in minor insertions, replacements, or deletions in a highly targeted manner (Esvelt and Wang, 2013). Genome editing with these nucleases is different from silencing the gene of interest by short interfering ribonucleic acid (RNA) in that the engineered nuclease is able to modify DNA-binding specificity and therefore can, in principle, cut any targeted position in the genome and introduce modification of the endogenous sequences for genes that are impossible to specifically target by conventional RNAi. But even with RNAi, JR Simplot has petitioned for deregulation of their 'Innate' technology based on RNAi suppression of undesirable traits in potatoes on the idea that their potatoes do not contain any transgenes. This is expanded on in another part of this encyclopedia.

The above approaches and evolving tools have tremendous capabilities of introducing very targeted modifications that call into question the notion of 'genetic engineering' and present a problem for regulatory authorities if they, without justification, decide they need to capture them for review as it is, for all intents and purposes, impossible to detect, so enforcing oversight proves to be a challenge. These new products and approaches on the horizon require a reassessment of appropriate criteria to manage risk while ensuring that the development of innovative technologies and processes is encouraged to provide value-added commodities for the consumer.

Other systems, such as synthetic biology (the design and construction of new biological parts, devices, and systems) and genome-scale engineering, are being enabled through advances in high-throughput DNA sequencing, and large-scale biomolecular modeling of metabolic and signaling networks will be contributors to food and agriculture production systems in the future.

Current US Regulations

The United States has been grappling with these regulatory issues considerably longer than most other countries. It also has the largest stake in the technology. Regulations in other jurisdictions, including the European Union (EU), Australia/New Zealand Authority, India, Japan, China, and South American and African countries, are still evolving and are being influenced by the US experience.

At the federal level, the United States has attempted, with mixed results, in developing a coordinated, risk-based system to ensure that new biotechnology products are safe for the environment and human and animal health. However, the trigger for oversight in all instances is still the process of genetic modification. The United States uses health and safety laws that were in the books before the advent of modern biotechnology to review genetically engineered (GE) products. To date, the United States has not issued any new legislation for these products. Established as a formal policy in 1986, the Coordinated Framework for Regulation of Biotechnology (Federal Register, 1986, 51 FR 23302) describes the Federal system for evaluating products developed using modern biotechnology. The Coordinated Framework is based on health and safety laws developed to address specific product classes. The move from the laboratory to the field proved a challenge for the relevant agencies. In the short time that elapsed between the initial development of the capabilities of recombinant DNA technology, the controversy over this research shifted focus from the presumed risks associated with the possible escape of genetically modified organisms (GMOs) from research laboratories to the nature of the long-term environmental impact of GMOs that are intentionally released.

Under the Coordinated Framework, agencies that were responsible for regulatory oversight of certain product categories or for certain product uses are also responsible for evaluating those same kinds of products developed using genetic engineering. Three agencies share primary responsibility for regulating the organisms, products, and processes of recombinant DNA technology, irrespective of whether they are designed for closed systems or for environmental release: the Food and Drug Administration (FDA), the United States Department of Agriculture (USDA), and the Environmental Protection Agency (EPA) (Table 1). Regulations under the Occupational Safety and Health Administration cover those working with rDNA, whereas the Department of Health and Human Services

Table 1 Oversight authority for agricultural biotechnology products

Agency	*Products regulated*
US Department of Agriculture (USDA)	Plant pests, plants, veterinary biologics, animals, fish, and arthropods
Environmental Protection Agency (EPA)	Microbial/plant pesticides, new uses of existing pesticides, and novel microorganisms
Food and Drug Administration (FDA)	Food, feed, food additives, veterinary and human drugs, and medical devices

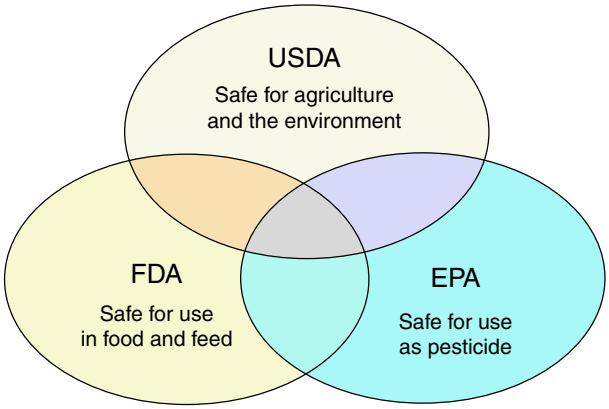

Figure 1 Distribution of federal oversight responsibility.

oversees the health of the general public. Their responsibilities are complementary and, in some cases, overlapping. The USDA–APHIS has jurisdiction over the planting of GE plants. The EPA has jurisdiction over planting and food and feed uses of pesticides engineered into plants. These are referred to as plant-incorporated protectants or PIPs. The FDA has jurisdiction over food and feed uses of all foods from plants. The agencies have developed a coordinated website to keep the public informed (Unified Biotechnology Website; **Figure 1**).

This framework has allowed the United States to build on agency experience with organisms and products developed using conventional techniques. Accordingly, the agencies base their analysis of oversight not principally on any presumed theoretical 'exotic' risks but rather exploit the vast cache of accumulated knowledge that has been amassed over years of research using highly developed scientific procedures for assessing field tests and planned introductions. Using such a scientific approach deduced from first principles is probably the most effective mechanism regulatory bodies can take in crafting effective regulations. The laws currently used to regulate the products of modern biotechnology are the Plant Protection Act (PPA); the Federal Food, Drug, and Cosmetic Act (FFDCA); the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA); and the Toxic Substances Control Act (TSCA). New regulations have been developed under these statutes as needed to address GE products developed. New regulations, policy statements, and guidelines will continue to be developed as needed.

The details of which items are regulated, such as organisms and processes, and how both may be regulated (time frames, permitting processes, and penalties) are written by each Agency that has the appropriate authority. All formal Federal regulations are published in the Federal Register and also in the Code of Federal Regulations, a large multivolume series. For example, those regulations for Agriculture and the USDA comprise 15 volumes and those governing biotechnology as overseen by APHIS-BRS are found in Volume 7, Section 340. The USA (under USDA–APHIS as described below) uniquely operates deregulation, allowing applications to request that a specific GM product be considered equivalent to crops modified using all other breeding techniques and therefore should no longer be regulated. All GM crops on the USA market currently have achieved a deregulated status.

Many states and local authorities were not satisfied with existing oversight and some 14 states and several municipalities enacted their own biotechnology legislation, many of which have since been modified or revoked. The most recent attempt was the required labeling of products that included 'GMO ingredients' under Proposition 37 in California. It went down to defeat following a concerted campaign that largely focused on the arbitrary nature and potential for capricious lawsuits that the draft language would facilitate.

Agencies must also adhere to the umbrella National Environmental Policy Act (NEPA), which is binding on all federal agencies. Depending on its intended use, a product may or may not be reviewed by all three regulatory agencies.

There have been 96 approvals for deregulation since 1990; these comprise examples from alfalfa, canola, corn, cotton, flax, rose, papaya, plum, potato, rice, soybean, squash, sugar beet, tobacco, and tomato. Those not already on the market, are likely to proceed to full commercial development. There are also 13 applications pending decision which represent the next group of GM crop varieties available on the market; these include alfalfa (1), apple (1) (nonbrowning), corn (1), cotton (1), creeping bentgrass (1), eucalyptus (1) (cold tolerance), potato (1) (reduced acrylamide), and soybean (6) (Information Systems for Biotechnology, 2013a,b). The most recently deregulated products are glyphosate tolerant canola (oil seed rape) (Pioneer/Monsanto), glyphosate tolerant corn, and a novel F1 hybrid seed production system for corn (Monsanto) (USDA, 2014).

The numbers of US GM field trial applications are shown by crop and GM trait in **Figures 2** and **3**, respectively. Each of these applications may cover a range of GM lines of a particular crop grown in one or more locations, and all commercial products will have been tested under this system over a period of several years and at several locations.

In 2013, there were 601 trials, with herbicide tolerant corn representing the largest category.

The United States Department of Agriculture

Scope for coverage is food and fiber products. Although its authority is as equally applicable to GM animals, plants, and microorganisms, it is in one sense outside the circle of ecological safety in that its primary concerns are the safety of crop plant and food animals and the safety and wholesomeness of food products.

The USDA has nine divisions that deal with biotechnology:

- The Agricultural Research Service (ARS)
- The Food Safety and Inspection Service (FSIS)
- The Animal and Plant Health Inspection Service (APHIS)
- The Agricultural Marketing Service (AMS)
- The Cooperative State Research Service (CSRS)
- Extension Service
- The National Agricultural Library
- The Forest Service (FS)
- The Economic Research Service (ERS).

The USDA's policy on the regulation of biotechnology, consistent with the overall federal policy, does not view GMOs as fundamentally different from those produced using traditional methods. The USDA considered that the products of the

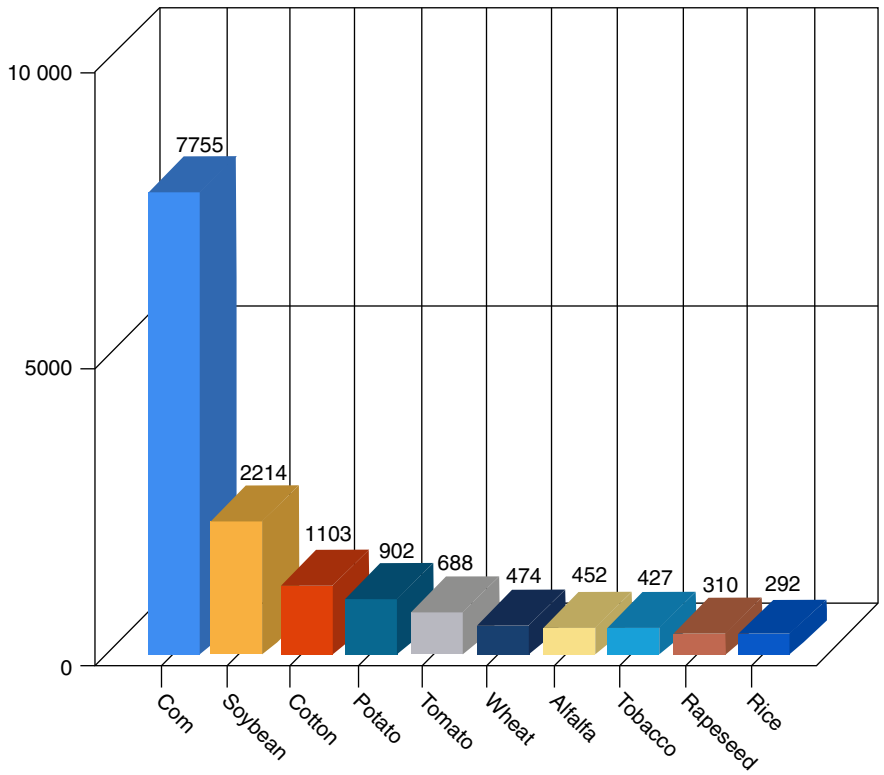

Figure 2 Numbers of field trial permits by crop. Data from Information Systems for Biotechnology, 2013b. Release Summary Data and Charts (1987–Present). Available at: http://www.isb.vt.edu/release-summary-data.aspx (accessed 03.03.14).

new techniques of biotechnology were in principle covered by regulations that had been implemented for existing technologies. They did, however, consider that the assessment of the products of the new technologies in some instances required specific information that necessitated the introduction of some new regulations and the updating of some existing ones.

Within the USDA, the Animal and Plant Health Inspection Service (APHIS) is responsible for protecting agriculture from pests and diseases. The Federal PPA (7 USC. §§7701 *et seq.*) is the primary statute under which the APHIS regulates agricultural biotechnology. Enacted in 2000, this statute replaced the former Federal Plant Pest Act. Originally intended to prevent the introduction and interstate movement of plant pests, the Plant Pest Act had been adapted by the APHIS to regulate GE plants so that they do not become 'plant pests.' The section within the APHIS with prime responsibility is the APHIS Biotechnology Regulatory Services APHIS-BRS. Under the PPA, the USDA–APHIS has regulatory oversight over products of modern biotechnology that could pose such a risk. Accordingly, the USDA–APHIS regulates organisms and products that are known or suspected to be plant pests or to pose a plant pest risk, including those that have been altered or produced through genetic engineering. These are called 'regulated articles.' A regulated article is defined in the APHIS regulations as "any organism which has been altered or produced through genetic engineering" if the donor organism, recipient organism, vector, or vector agent is a 'plant pest' (7 C.F.R. § 340.1). The APHIS defines a plant pest broadly to include 'any living stage' of insects, bacteria, fungi, viruses, or various other organisms that can damage or cause injury to plants or plant parts (7 C.F.R. §340.1). Many plant pathogens commonly used as vectors or promoters in agricultural biotechnology, such as *Agrobacterium* species and cauliflower mosaic viruses, are considered plant pests under the APHIS regulations (7 C.F.R. §340.2(a)). Use of any of these plant pests to make a transgenic plant makes that plant a regulated article. The agency may also designate any product of genetic engineering as a regulated article that the agency determines or has reason to believe is a plant pest (7 C.F.R. §340.1). The USDA–APHIS regulates the import, handling, interstate movement, and release into the environment of regulated organisms that are products of biotechnology, including organisms undergoing confined experimental use or field trials. Regulated articles are reviewed to ensure that, under the proposed conditions of use, they do not present a plant pest risk through ensuring appropriate handling, confinement, and disposal.

In 1993, with modifications in 1995 and 1997, the USDA introduced the final rule notification in lieu of permit process for GMOs that are field tested in accordance with specific safety criteria. The amendment simplifies procedures for the introduction of certain GE organisms, expedites review for certain determinations of nonregulated status, and adjusts procedures for the reporting of field tests conducted under notification to the biology of the test organisms. This enables the APHIS, when appropriate, to extend the existing determination of nonregulated status for new products that do not raise new risk issues. The USDA–APHIS regulations provide a petition process for the determination of

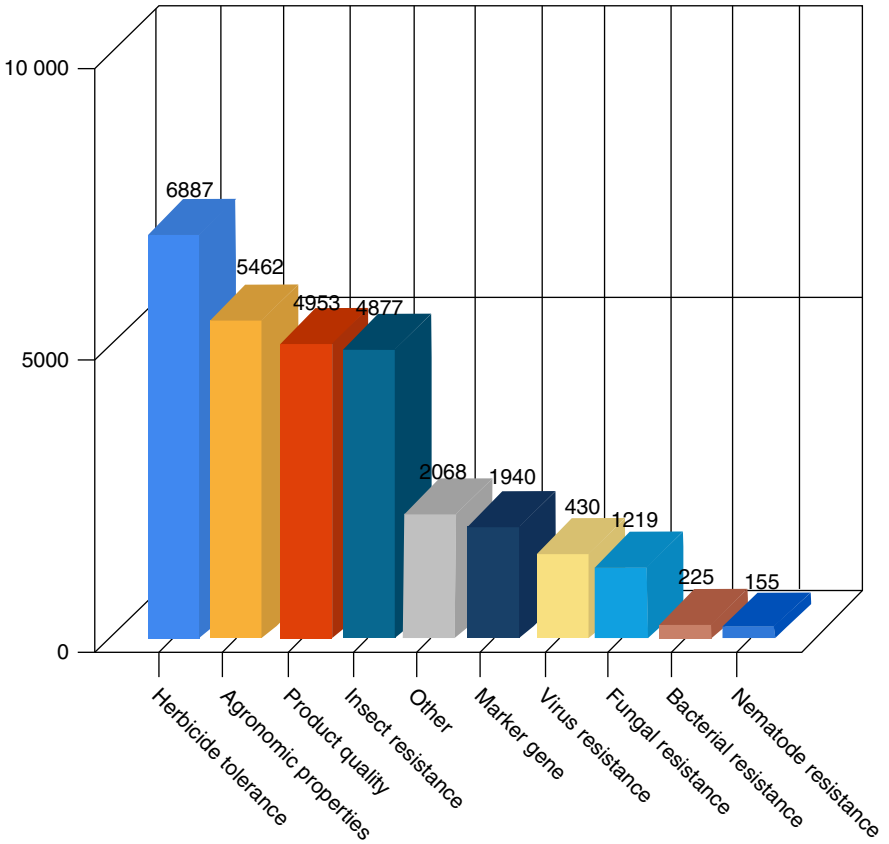

Figure 3 US field trial permits by trait. Data from Information Systems for Biotechnology, 2013b. Release Summary Data and Charts (1987–Present). Available at: http://www.isb.vt.edu/release-summary-data.aspx (accessed 03.03.14).

nonregulated status (USDA Petition). If a petition is granted, that organism will no longer be considered a regulated article and will no longer be subject to oversight by the USDA–APHIS. The petitioner must supply information such as the biology of the recipient plant, experimental data and publications, genotypic and phenotypic descriptions of the GE organism, and field test reports. The agency evaluates a variety of issues, including the potential for plant pest risk; disease and pest susceptibilities; the expression of gene products, new enzymes, or changes to plant metabolism; weediness and impact on sexually compatible plants; agricultural or cultivation practices; effects on nontarget organisms; and the potential for gene transfer to other types of organisms. A notice is filed in the Federal Register and public comments are considered on the environmental assessment and determination written for the decision on granting the petition. Copies of the USDA–APHIS documents are available to the public.

One exception to the notification process described above is for plants that have been modified GM to produce pharmaceutical or industrial products (40 C.F.R. § 340.3(b)(4)(iii)). These plants require a permit before field-testing or interstate shipment. APHIS policy is to inspect all field trials involving such organisms at least annually, and the Agency has stated that such organisms would never be eligible for 'deregulation' (White, 2000). Currently, test plots for crops engineered to produce are regulated by the APHIS permit system.

The USDA regulations require developers to have clearly written procedures in order to handle wastes properly and maintain production and control records. Plant-made pharmaceuticals also come under the US FDA purview. The FDA monitors the manufacturing process as well as the purity and consistency of the products under its 'good manufacturing practices' guidelines. Nevertheless, both the USDA and the FDA recognize that this is a new application of the technology and are in the process of coming up with new guidance, specifically for pharmaceutical plants.

The growing and harvesting of the crop itself must comply with principles of confinement, which essentially means keeping the crop and its products on the land where it was grown until removed for processing with no inadvertent exposure to the public and minimal exposure of products to workers and the environment. Adequate analytical methods for detection of expression (i.e., protein) products must be demonstrated and all confinement systems and procedures must be based on sound scientific principles. Identity preservation within a closed loop system to prevent comingling of pharm crops with food crops will be a prime directive for industry as well as regulatory agencies.

In addition to the above, under the NEPA, the USDA has a responsibility for ensuring ecological safe utilization of crops, livestock, and veterinary products produced both from traditional and recombinant DNA methods. The FSIS assures the safety and wholesomeness of food products.

More than 10 000 field tests, involving more than 200 organisms at thousands of sites throughout the United States, have been analyzed by the USDA. The agency has assessed the biotech plants for their efficacy, performance, and suitability for release in the environment. Globally, approximately tens of thousands of field trials have been conducted on hundreds of organisms in 45 countries (International Field Test Sources, 2007). There has not been a single report of any unexpected or unusual outcome. The APHIS also issues licenses and permits for production, importation, sale, and experimental use of various types of biological products. Specific information that must be submitted for GMOs and products includes detailed information on stability, genetic constructs and vectors, and the effects of any insertions and deletions in the organism.

Some of the more recent deregulations include novel products, such as maize genetically modified to produce a common enzyme called alpha-amylase that breaks down starch into sugar, thereby facilitating a vital step in biomass conversion in ethanol production and apples with RNAi-suppressed oxidizing enzymes to prevent browning. There also has been controversy in some of the processes. In 2007, a court rescinded the approval of glyphosate-tolerant alfalfa, which had been deregulated in 2005 on the grounds that the agency failed to complete an Environmental Impact Statement (EIS) addressing the issue of gene flow and coexistence between GE and conventional varieties. In 2010, the USDA completed the EIS and three alternatives were proposed (1) no deregulation, (2) complete deregulation, and (3) partial deregulation with conditions and restrictions. In a highly unusual move the USDA Secretary Vilsack met with interest groups to try to foster coexistence and avoid lawsuits. In 2011, the second alternative was chosen and GT alfalfa was again deregulated.

In 2008, the USDA revisited the deregulation process and proposed new rules to be phased into use. They proposed a multitiered permit system for field-testing bioengineered plants wherein higher risk products were subject to tighter controls; they also considered conditional decisions and postmarketing monitoring requirements for commercialization of certain bioengineered plants; they recommended more coordination with the FDA and the EPA to include early food safety assessments to address low-level intermittent presence of unapproved traits in the food supply; and proposed new policies for field-testing and commercializing plant-made pharmaceuticals and plant-made industrial products. There was significant push back by the scientific community based on the lack of science underpinning the review process and the trigger points for regulatory overview. Despite providing a comprehensive and thorough prolog that quite clearly delineated the history, issues, and process involved in promulgating the proposed regulations, the suggested amendments that appeared in the Federal Register (2008a,b) in October 2008 had little basis in science or proportionality. The proposed regulations placed little value on precedent, experience, or history basically reducing the regulatory process to assessment on a case-by-case basis. If implemented, this would have greatly increased the burden of proof and placed such an onus on meeting regulatory requirements that it may very well have had a detrimental effect on all agricultural biotech research.

The Environmental Protection Agency

The EPA claims that its biotechnology regulatory program is based on five important principles that guide its decision-making policy. The principles are – using sound science, ensuring transparency of the decision-making process, maintaining consistency and fairness, collaborating with its regulatory partners, and building public trust.

Under the NEPA, the EPA has broad jurisdiction over environmental impact. It mostly considers GMOs under the aegis of the 'TSCA and the FIFRA. In general, the TSCA will not be triggered if the microbes are used to produce foods, additives, drugs, vaccines, cosmetics, or medical devices and are regulated by the FDA or the USDA. Other than those listed exemptions, all other new or new-use chemical end products from microorganisms, which themselves may be considered new, are subject to the TSCA. Consent orders and negotiated agreements are used as the mechanisms to cover environmental introductions.

The FIFRA mandates the registration of pest-control products and 'economic poisons' before production and sale. To test a product, an applicant must submit complete data. Product evaluation includes the equivalent to an Environmental Assessment or EIS. Since 1984, notification of intent to field-test GMOs and nonengineered, nonindigenous pathogenic and nonpathogenic microorganisms was required, regardless of testing site size.

The EPA currently regulates chemical pesticides and biopesticides that are externally applied to plants. In the 1990s, the agency expanded its federal regulatory powers over the characteristics of plants that help plants to resist diseases and pests. The agency coined a new term for these characteristics, calling them 'plant pesticides.' All plants are able to prevent, destroy, repel, or mitigate pests or diseases. That ability occurs naturally, and some crops have been bred for resistance to specific pests. The EPA proposed to single out regulation for those pest-resistant qualities that were transferred to the plant through recombinant DNA technology. Eleven Professional Scientific Societies took grave objection to the suggested regulations and they responded by developing a document entitled 'Appropriate oversight for plants with inherited traits for resistance to pests: A report.' They determined that evaluation of the safety of substances in plants should be based on the toxicological and exposure characteristics of the substance and not on whether the substance confers protection against a plant pest. A compromise was reached, and the EPA now regulates 'PIP.'

The PIPs Rules were issued on 17 January 2001. The rules consider the impact on beneficial insects and nontarget organisms; toxicity of pesticidal compound; safety for human consumption; and ecological hazards and insect resistance. The specific tests for the FIFRA PIPs clearance are wildlife exposure studies for PIPs on nontarget organisms; feeding studies on beneficial insects, including honeybees, ladybird beetles, lacewings, earthworms, birds, fish, and mammals at 10–100 times the concentration; and environmental fate, that is, how long it takes for the PIP protein to degrade in plant material left on or in the soil. Reviews are conducted on a case-by-case basis based on the product and the risk and not the means by which the organism was created. However,

interestingly, despite this assertion, no experimental use permits (EUPs) are required for undirected mutagenesis, most transconjugants, and plasmid-cured strains, yet EUPs are required for all live rDNA GMOs, irrespective of product or risk.

Under the TSCA, the EPA acquires information in order to identify and regulate potential hazards and exposures. The TSCA applies to the manufacturing, processing, importation, distribution, use, and disposal of all chemicals in commerce, or intended for entry into commerce, that are not specifically covered by other regulatory authorities (e.g., substances other than food, drugs, cosmetics, and pesticides). The TSCA's applicability to the regulation of products of biotechnology is based on the interpretation that organisms are chemical substances under the TSCA. The EPA's TSCA Biotechnology Program of the Office of Prevention and Toxic Substances currently regulates microorganisms intended for general industrial uses. The program conducts a premarket review of 'new' microorganisms, i.e., microorganisms formed by deliberate combinations of genetic material from organisms classified in different taxonomic genera. Developers must notify the EPA 90 days before manufacture or 60 days before field-testing of a product regulated by the TSCA. Proposed modifications are issued in the federal registrar for comment. For example, on 5 September 2012, the EPA issued a notification proposing to add two microorganisms (specific strains of the fungus *Trichoderma reesei* and specific subspecies of the bacterium *Bacillus amyloliquefaciens*) to the list of 10 recipient microorganisms (40 CFR 725.420) that are eligible for exemptions from full chemical notification requirements under the TSCA. They took comments on the proposal until 5 November 2012.

The EPA also sets tolerance limits for residues of pesticides on and in food and animal feed, or establishes an exemption from the requirement for a tolerance, under the FFDCA.

Meanwhile, the benefits of biotechnology crops experienced by larger-scale farmers in both industrialized nations and lesser developed countries are already considerable. Research by Brookes and Barfoot (2012a) showed that in 2010 the direct global farm income benefit from biotech crops was US$14 billion. They estimated that this is equivalent to having added 4.3% to the value of global production of the four main crops of soybeans, maize, canola, and cotton. In addition, in their retrospective analysis over the 15 years, from 1996 to 2010, they estimated that farm incomes increased by US$78.4 billion. Biotech crops are, moreover, making important contributions to increasing global production levels of the four main crops. They have, for example, now added 97.5 million tons and 159.4 million tons, respectively, to the global production of soybeans and maize since the introduction of the technology in the mid-1990s. (Brookes and Barfoot, 2012b) In addition, the environmental footprint associated with pesticide use was reduced by 15.4%; there was a reduction in carbon dioxide emissions in 2010, equivalent to taking nearly 10 million cars off the road for a year.

Biotech, primarily herbicide-tolerant crops, facilitates the switch to reduced-till, or conservation, agriculture, which means healthier soil, with reduced erosion and far less carbon dioxide release. In general, cultivation is not a sustainable practice. It is energy intensive and exposes soil to wind and water erosion. It allows rain to compact the soil and increases the oxygen content of the soil, allowing organic matter to oxidize away. In turn, lower organic matter in the soil allows more compaction and more nutrient loss. Pesticide use fell by more than 286 million kg (− 7.8%: equivalent to approximately 40% of the annual volume of pesticide-active ingredient applied to arable crops in the EU). Less spraying means fewer tractor passes, contributing to lower carbon dioxide emissions. Insect-resistant maize also has a collateral effect – less insect damage results in much less infection by fungal molds, which reduces mycotoxins that are known health risks causing problems such as liver cancer to humans and animals. The only 'natural' way to control those fungi is the use of copper sulfate, which has one of the highest toxic hazard ratings of acceptable pesticides and is selected for antibiotic-resistant bacteria in the soil as expanded in another part of this encyclopedia.

Food and Drug Administration

The FDA regulates biotechnology under the authority of the Food, Drug, and Cosmetic Act (FDCA) and the Public Health Services Act. The agency has a mandate to ensure efficacy and safety of food and pharmaceutical products. The agency has a major responsibility in biotechnology in that the majority of the current market share of biotechnology products passes through the agency for review, and it has already reviewed thousands of biotechnology products.

The FDA is responsible for ensuring the safety and proper labeling of all plant-derived foods and feeds, including those developed through bioengineering. All foods and feeds, whether imported or domestic and whether derived from crops modified by conventional breeding techniques or by genetic engineering techniques, must meet the same rigorous safety standards. Under the FDCA, it is the responsibility of food and feed manufacturers to ensure that the products they market are safe and properly labeled. Generally, whole foods, such as fruits, vegetables, and grains, are not subject to premarket approval. The primary legal tool that the FDA has successfully used to ensure the safety of foods is the adulteration provisions of section 402(a)(1). The Act places a legal duty on developers to ensure that the foods they present to consumers are safe and comply with all legal requirements. The FDA has authority to remove a food from the market if it poses a risk to public health. Foods derived from new plant varieties developed through genetic engineering are regulated under this authority. A second section of the Act that the FDA relies on is the food additive provision (section 409). Under this section, substances that are intentionally added to food are food additives, unless the substance is generally recognized as safe (GRAS). Food additives are subject to review and approval by the FDA before they may be used in food. When requested to do so, the FDA also reviews and affirms the GRAS status of food ingredients.

In May 1992, the FDA issued a policy statement on regulating biotechnology food products. The FDA requires premarket review only for foods into which substances are intentionally introduced, significantly changing the structure, function, or amount currently found in the food (Statement

of Policy: Foods Derived From New Plant Varieties (1992)). If a new food product developed through biotechnology does not contain substances that are significantly different from those already in the diet, it does not require premarket approval. To help sponsors of foods and feeds derived from GE crops comply with their obligations, the FDA encourages them to participate in its voluntary consultation process. All foods and feeds from GE crops currently on the market in the United States have gone through this consultation process. With one exception, none of these foods and feeds was considered to contain a food additive and so did not require approval before marketing. The consultation process under the FDA's 1992 Statement of Policy was updated in 1996 and 1997. On a number of occasions, the FDA stated that they would publish a proposed rule mandating that developers of bioengineered foods and animal feeds notify the agency when they intend to market such products and that they would require that specific information be submitted to help determine whether the foods or animal feeds possess any potential safety, labeling, or adulteration issues. However, consultation still remains voluntary (Food and Drug Administration, Center for Food Safety and Applied Nutrition (FDA/CFSAN), 2000).

On the 'labeling' issue, the FDA's policy guidelines state that foods produced through biotechnology will be subject to the same labeling laws as all other foods and food ingredients. Labeling would be required for biotech products in some instances, but not because the products were made using biotech. The FDA requires that labeling of a food or food ingredient or additive be truthful and not misleading and that the product be declared by its common or usual name. In general, the information on the label pertains to the composition and attributes of the food or food ingredients or additive but not to the details of agricultural practices or the manufacturing process. The question of whether foods derived from organisms containing recombinant DNA should be specially labeled has received a great deal of attention. The FDA's (1992) approach to the labeling of foods, including those GE or otherwise novel, is that the label must be accurate and 'material' to it. There are only two situations in which the FDA can require that a transgenic origin or ingredient be disclosed on the food label (1) the FDA may mandate the disclosure of facts on a product label that relate to material consequences, which can follow the consumption of a food (e.g., kidney beans that must be soaked and cooked before eating) and (2) the FDA can require that a label reveal facts necessary to correct or balance other representations made by the manufacturer or seller. Accordingly, labeling is required "if a food derived from a new plant variety differs from its traditional counterpart such that the common or usual name no longer applies, or if a safety or usage issue exists to which consumers must be alerted." The policy statement also emphasizes that no premarket review or approval is required unless characteristics of the biotech food explicitly raise safety issues and that – in as much as the genetic method used in the development of a new plant variety does not meet either of the two criteria for 'materiality' – the FDA cannot require the labeling to include this information. Obviously, many of the novel nutritionally enhanced foods expected on the market in the next few years will be labeled as they will differ from their traditional counterparts, and in most instances the company marketing them will want to proclaim their enhanced nutritional value.

In 2006, to address the possibility that material from a new plant variety intended for food use might inadvertently enter the food supply before its sponsor has fully consulted with the FDA, the FDA announced the availability of a draft guidance document entitled 'Guidance for Industry: Recommendations for the Early Food Safety Evaluation of New Non-Pesticidal Proteins Produced by New Plant Varieties Intended for Food Use.' It discussed the early food safety evaluation of new proteins in new plant varieties, particularly in new bioengineered varieties that are under development for possible use as food for humans or animals. The draft guidance also described procedures for communicating with the FDA about this evaluation. The issuance of draft guidance was proposed in August 2002 in a Federal Register Notice (67 FR 50578) published by the Office of Science and Technology Policy as part of proposed Federal actions to update field test requirements and to establish early voluntary food safety evaluations for new proteins produced by bioengineered plants.

They opined that rapid developments in genomics are resulting in dramatic changes in the way new plant varieties are developed and commercialized. Scientific advances are expected to accelerate, leading to the development and commercialization of a greater number and diversity of bioengineered crops. As the number and diversity of field tests for bioengineered plants increase, the likelihood that cross-pollination due to pollen drift from field tests to commercial fields and commingling of seeds produced during field tests with commercial seeds or grain may also increase. This could result in low-level presence in the food supply of material from new plant varieties that have not been evaluated through FDA's voluntary consultation process for foods derived from new plant varieties (referred to as a 'biotechnology consultation' in the case of bioengineered plants). The FDA believes that any potential risk from the low level presence of such material in the food supply would be limited to the possibility that it would contain or consist of a new protein that might be an allergen or toxin.

Although the FDA has not found and does not believe that new plant varieties under development for food and feed use generally pose any safety or regulatory concerns, this guidance is consistent with the FDA's policy of encouraging communication early in the development process for a new plant variety. Such communication helps to ensure that any potential food safety issues regarding a new protein in such a new plant variety are resolved before any possible inadvertent introduction into the food supply of material from that plant variety.

Depending on its intended use, a product may or may not be reviewed by all three regulatory agencies. A food crop plant developed using genetic engineering to produce a pesticide in its own tissue provides an example that is reviewed by all three regulatory agencies. A common example of this type of product is Bt corn, which has incorporated a gene isolated from the soil bacterium *Bacillus thuringiensis* (Bt). The *Bt* gene encodes a pesticidal protein (Cry). The USDA–APHIS under the PPA regulates the corn as a regulated article based on the procedures used to introduce or express the *Bt* gene. The

USDA–APHIS oversight begins early in the development cycle and continues until the developer applies for and is granted nonregulated status for the plant because it can be shown that the plant is not a plant pest. Until such time as the developer is granted nonregulated status for the plant, the USDA–APHIS oversees the transportation (including importation), field-testing, and disposal of the plant. Developers of Bt crops also consult with the FDA about possible other, unintended changes to the food or feed, for example, possible changes in nutritional composition or levels of native toxicants. Although this consultation is voluntary, all of the food/feed products commercialized to date have gone through the consultation process. The consultation with the FDA serves to ensure that safety or other regulatory issues that fall within the agency's jurisdiction, including appropriate labeling of the food, are resolved before commercial distribution.

When an unregulated event falling under all three jurisdictions is detected in commercial distribution, all three coordinate to mitigate the misadventure. For example, in February 2008, the three agencies coordinated efforts following notification by Dow AgroSciences' subsidiary Mycogen that the company detected extremely low levels of an unregistered GE plant-incorporated protectant (PIP) in three of its commercial GE hybrid corn seed lines. They quickly determined that the unregistered product produces proteins that are identical to a registered product and issued a statement that the USDA, EPA, and the FDA have concluded that there are no public health, food, or feed safety concerns. Additionally, the USDA and the EPA have determined that the unregistered GE corn PIP poses no plant pest or environmental concerns (Event 32, 2008). **Table 2** outlines some examples of shared coordination.

Animal Biotechnology

Biotechnology, as it relates to animals, is largely comprised of three main thrust areas, namely biologics (including vaccines and 'therapeutics') and agricultural and biomedical applications.

As with plants, the two principal agencies that oversee animal biotech applications are the USDA and the FDA. Within the USDA, primary jurisdiction for biologics lies under the Virus, Serum, Toxin Act. The USDA–APHIS Veterinary Services inspect biologics production establishments and license veterinary biological substances, including animal vaccines that are products of biotechnology. Within the FDA the Center for Veterinary Medicine (CVM) is the primary center responsible for approving recombinant products. For example, recombinant bovine somatotropin (rBST), a growth hormone injected into dairy cows, fell under CVM jurisdiction. The CVM considered the additions of rBST (or the genetic modifications involved in producing rBST) to constitute the addition of an animal drug, making the product subject to its premarket approval authority.

Although any transgenic animal is yet to be approved for human consumption, regulations are in place to cover their use. As with plants, the principal federal regulation of transgenic animals and fish is governed by the Food, Drug, and Cosmetics Act.

As far back as 1986, the FDA asserted jurisdiction over transgenic animals and fish on the grounds that the transgene and any expressed proteins affect the 'structure and function' of the receiving animal analogous to the modalities of alternative veterinary drug formulations. This gene-based modifications of animals for production or therapeutic claims fall under CVM regulation as new animal drugs. They work in consultation with the other FDA Centers for food and feed safety evaluation. The FDA jurisdiction has been upheld by the federal courts. Perhaps more so than for plants, the principal focus for transgenic animal production is their use as bioreactors for the production of biotherapeutics in milk, serum, and other bodily fluids. So it makes logical sense that they would be regulated as Institutional New Drugs under CVM. However, faced with regulatory decision making regarding the ever-evolving GM and cloning pipeline, the FDA asked the National Research Council (NRC) to identify and prioritize science-based concerns posed by animal biotechnology. The NRC released its report, Animal biotechnology: Science-based concerns to the public on 21 August 2002, drawing the attention of scientists, the biotech industry, nongovernmental organizations, and the national media.

Their concerns fell into three areas – medical, food, and environmental. On the medical side, the principal concerns

Table 2 Example of coordination of oversight between agencies

New trait/crop	*Agency*	*Review*
Insect resistance in food crop (Bt corn)	USDA	Agricultural and environmental safety
	EPA	Environmental, food/feed safety of pesticide
	FDA	Food/feed safety
Herbicide tolerance in food crop (glyphosate-tolerant soybeans)	USDA	Agricultural and environmental safety
	EPA	New herbicide use
	FDA	Food/feed safety
Herbicide tolerance in ornamental crop (glufosinate-tolerant azaleas)	USDA	Agricultural and environmental safety
	EPA	
	FDA	New herbicide use
Modified oil in food crop (omega three canola)	USDA	Agricultural and environmental safety
	EPA	
	FDA	Food/feed safety
Modified flower color (purple carnations)	EPA	Agricultural and environmental safety

were modification of animals for biomedical purposes, especially xenotransplantation mobilization of new infectious agents. On food issues, they focused on new proteins, and food safety concerns posed by biological activity, allergenicity, or toxicity that they determined should be evaluated on a case-by-case basis. The key issue regarding cloned animals is whether and to what degree the genomic reprogramming results in altered gene expression that raises food safety concerns. They concluded that although it is difficult to quantify concerns without data comparing the composition of food products from cloned and noncloned animals, there is no current evidence that food products derived from adult somatic cell clones or their progeny present a safety concern. Their greatest concern was surprisingly environmental, specifically the potential for GM organisms to escape and become established in the natural environment. They specifically considered that the existing regulatory framework might not prove adequate, particularly with regard to transgenic arthropods. Understandably, not only were there concerns regarding the potential for this technology to cause pain, physical and physiological distress, behavioral abnormality, and health problems but also noted that potential existed to alleviate or reduce those problems. Broadly, they expressed concern about the technical capacity of the agencies to address potential hazards.

As noted under CVM, investigational applications are filed for genetic modifications under the authority of an investigational new animal drug exemption (INAD) or a similar provision. The INAD regulations are published in the Code of Federal Regulations, Title 21, Part 511.1(b). As part of the INAD submission, researchers must document their plans regarding the disposition of all investigational animals after their participation is completed. This is important in the case of food animal species where, with a showing of adequate safety data, the sponsor may request disposition of animals by slaughter for food or for processing into animal feed components. Although no transgenic animals have been approved for use as human food, a very limited number have been approved for rendering into animal feed components. In September 2008, the FDA published for public comment proposed regulations that crystallized the notion that every transgenic animal expressing a novel trait would be subject to the procedures and regulations for drug approval. In January 2009, the FDA issued a final guidance for industry on the regulation of GE animals. The FDCA defines ''articles (other than food) intended to affect the structure or any function of the body of man or other animals'' as drugs. An rDNA construct that is in a GE animal and is intended to affect the animal's structure or function meets the definition of an animal drug, irrespective of whether the animal is intended for food or used to produce another substance. Under this guidance, developers of these animals must demonstrate that the construct and any new products expressed from the inserted construct are safe for the health of the GE animal and, if they are food animals, for consumption. Many consider that this 'new drug' paradigm does not fit transgenic animals well. Miller (2008) proposed that a better model was the approach taken by the Center for Food Safety and Nutrition that placed the burden of ensuring safety of foods and food ingredients on those who produced them.

In December 2003, California found itself in the national spotlight when it became the only state to ban the sale of a GE pet fish, called the GloFish, based on the potential for negative ecological impact.

The first transgenic animal that is more likely to receive commercial approval is a salmon from the AquAdvantage Company, which reaches maturity twice as fast as the wild type. The fish is an Atlantic salmon that contains the Chinook salmon growth hormone gene, a stably integrated α-form of the *opAFP-GHc2* gene construct at the α-locus in the EO-1α line under the control of an antifreeze protein promoter from the ocean pout permitting year-round expression (Staveley, 2010). The AquAdvantage Salmon reaches market size twice as fast as traditional salmon, but they do not grow to be larger than their conventional counterparts. The salmon are grown in land-based contained tanks and with reproductively sterile females, which precludes the threat of interbreeding among themselves or with native populations, eliminating the risk to wild populations or the environment.

Animal Clones

On 15 January 2008 (CVM and Animal Cloning, 2008) after years of detailed study and analysis, the FDA issued an advisory that concluded that meat and milk from clones of cattle, swine, and goats, and the offspring of clones from any species traditionally consumed as food, are as safe to eat as food from conventionally bred animals. Interestingly, they considered that there was insufficient information for the agency to reach a conclusion on the safety of food from clones of other animal species, such as sheep. The release was advisory rather than regulatory as withholding of clones from the food and feed supply was voluntary because no regulations exist banning this practice.

The advisory consisted of three documents on animal cloning outlining the agency's regulatory approach – a risk assessment, a risk management plan, and guidance for industry. The documents were originally released in draft form in December 2006. Since then, the risk assessment has been updated to include new scientific information. That new information reinforces the food safety conclusions of the drafts, namely that milk and meat products from cloned cattle, pigs, and goats are safe for consumers to eat because cloned cattle between 6 and 18 months of age are 'virtually indistinguishable' from their conventional parents and can give birth to healthy offspring. The agency said that any risk was small, given that the group that could pose problems, live neonatal clones, is unlikely to enter the food supply; it poses an extremely limited risk for consumption. The proposed plan outlines measures that the FDA might take to address the risks that cloning poses to animals involved in the cloning process. These risks have been observed in other assisted reproductive technologies currently in use in common agricultural practices.

The draft guidance for industry addresses the use of food and feed products derived from clones and their offspring. The guidance is directed at clone producers, livestock breeders, and farmers and ranchers purchasing clones. It provides the agency's current thinking on use of clones and their offspring in human food or animal feed.

In the draft guidance, the FDA does not recommend any special measures relating to human food use of offspring of clones of any species. Because of their cost and rarity, clones will be used as any other elite breeding stock – to pass on naturally occurring, desirable traits, such as disease resistance and higher quality meat, to production herds. Because clones will be used primarily for breeding, almost all of the food that comes from the cloning process is expected to be from sexually reproduced offspring and descendents of clones and not the clones themselves.

International Perspective on Food Safety

Biotechnology is a worldwide industry. In the case of GM crops alone, more than 100 000 field trials have been done on more than 200 crops in more than 50 countries, including many of the 27 countries of the EU. Despite the fact that almost 80% of these trials take place in the United States, the regulatory issues are of concern to all, and biotechnology issues are front and center in many international fora. For instance, several nations are working on the United Nations' (UN) Biosafety Protocol. The purpose of the protocol is to protect biological diversity from potential adverse effects resulting from the transboundary movement of living modified organisms, including those made through biotechnology. It also addresses the needs of developing countries to develop the capacity to assess and manage potential risks. The Codex Alimentarius Commission has established the Codex Committee on Food Labeling to arrive at a common international position on labeling. A number of countries and regions have established threshold levels for labeling. For approved varieties, commonly tolerance thresholds are established below which a product does not have to be labeled as containing or derived from GMOs. Threshold levels vary for each legislation. Since 2004, the labeling threshold for food products in the EU is 0.9%. Current EU regulations demand control through analysis and traceability. Food and feed products that contain or are derived from GMOs must be labeled. For products that are highly refined, documentation of their conventional, non-biotech source material is now required. The labeling threshold in Japan is 5%, in South Korea 3%, and in Australia and New Zealand 1%.

However, notwithstanding labeling requirements in different jurisdictions, the consensus of scientific opinion and evidence is that the application of GM technology introduces no unique food/feed safety concerns and that there is no evidence of harm from those products that have been through a regulatory approval process. This conclusion has been reached by numerous national and international organizations (e.g., Food and Agriculture Organization/World Health Organization of the UN (FAO/WHO), Organisation for Economic Cooperation and Development (OECD), EU Commission, French Academy of Sciences, NRC of the National Academy of Sciences, Royal Society of London, and Society of Toxicology).

Some summary statements of these leading science organizations include: "No effects on human health have been shown as a result of the consumption of such foods by the general population in the countries where they have been approved."(WHO); "No adverse health effects attributed to genetic engineering have been documented in the human population." (National Academy of Sciences); "The science is quite clear: crop improvement by the modern molecular techniques of biotechnology is safe." (American Association for the Advancement of Science); "There is no scientific justification for special labeling of bioengineered foods. Bioengineered foods have been consumed for close to 20 years, and during that time, no overt consequences on human health have been reported and/or substantiated in the peer-reviewed literature." (American Medical Association); "No scientific evidence associating GMOs with higher risks for the environment or for food and feed safety than conventional plants and organisms." (European Commission); "All criticisms against GMOs can be largely rejected on strictly scientific criteria." (French Academy of Science); "In consuming food derived from GM plans approved in the EU and in the USA, the risk is in no way higher than in the consumption of food from conventionally grown plants. On the contrary, in some cases food from GM plants appears to be superior in respect to health." (Union of German Academics and Scientists); and "Foods can be produced through the use of GM technology that are more nutritious, stable in storage and in principle, health promoting – bringing benefits to consumers in both industrialized and developing nations." (Joint Statement of the Science Academies of Brazil, China, India, Mexico, Third World Academy of Sciences, Royal Society of the UK and the National Academy of Sciences of the US).

There now exists a significant body of evidence that demonstrates that all forms of plant breeding introduce a variety of changes in DNA, ranging from point mutations and single base pair deletions and insertions, loss or acquisition of genes, to changes in numbers of whole chromosomes. When compared with classical plant breeding methods, transgene insertion has been observed to produce less unintended DNA modification. In contrast to traditionally bred crops, a rigorous safety-testing paradigm has been developed and implemented for GM crops that utilizes a systematic, stepwise, and holistic safety assessment approach (Cockburn, 2002). The resultant science-based process focuses on a classical evaluation of the toxic potential of the introduced novel trait and the wholesomeness of the GM crop. In addition, detailed consideration is given to the history and safe use of the parent crop as well as that of the gene donor(s). The overall safety evaluation is conducted using the process known as 'substantial equivalence,' a model that is entrenched in all international crop biotechnology guidelines. This provides the framework for a comparative approach to identify the similarities and differences between the GM product and an appropriate comparator that has a known history of safe use. By building a detailed profile on each step in the transformation process (from parent to new crop) and by thoroughly evaluating the significance, from a safety perspective, of any differences that may be detected between the GM crop and its comparator, a comprehensive matrix of information is constructed. This information is used to reach a conclusion about whether food or feed derived from the GM crop is as safe as food or feed derived from its traditional counterpart or the appropriate comparator. Using this approach in the evaluation of more than 50 g crops that have been approved worldwide, the conclusion has been reached that foods and feeds derived

from GM crops are as safe and nutritious as those derived from traditional crops. The lack of any proven adverse effects resulting from the production and consumption of GM crops grown on more than one billion cumulative ha over the past 17 years supports these safety conclusions.

The US NRC in 'Genetically Modified Pest-Protected Plants: Science and Regulation' (NRC, 2000) determined that no difference exists between crops modified through modern molecular techniques and those modified by conventional breeding practices. The NRC emphasized that the authors were not aware of any evidence suggesting that foods on the market today are unsafe to eat because of genetic modification. In fact, the scientific panel concluded that growing such crops could have environmental advantages over other crops.

In a 2003 position paper, the Society of Toxicology (SOT, 2003) corroborated this finding and noted that there is no reason to suppose that the process of food production through biotechnology leads to risks of a different nature than those already familiar to toxicologists or to risks generated by conventional breeding practices for plant, animal, or microbial improvement. It is, therefore, important to recognize that it is the food product itself, rather than the process through which it is made, that should be the focus of attention in assessing safety.

The OECD and the WHO have embraced the concept of substantial equivalence as the cornerstone of safety assessment for GM foods and crops. The most complex regulatory and political situation is in the EU, especially with regard to labeling for consumers. The OECD's Working Group on Harmonization of Regulatory Oversight in Biotechnology decided at its first session, in June 1995, to focus its work on the development of consensus documents that are mutually recognized as among member countries. These consensus documents contain information for use during the regulatory assessment of a particular product. The consensus documents comprise technical information for use during the regulatory assessment of products of biotechnology and are intended to be mutually recognized among OECD member countries. These documents focus on the biology of organisms (such as plants, trees, or microorganisms) or introduced novel traits.

Variations due to breeding and the application of modern biotechnology have been studied frequently by scientific experts sponsored by organizations such as the UN FAO, the European Commission, the Royal Society, and the US National Academy of Sciences. In each case, the conclusions were that modern biotechnology is no more likely than conventional breeding to produce unintended effects. Indeed, many expert reviews have concluded that the greater precision and more defined nature of the changes introduced into crops via modern biotechnology may actually be safer than changes produced by conventional plant breeding.

Studies have also shown that GM crops are often more closely related to the isogenic parental strain used in their development than to other members of the same genus and species with respect to their transcriptomic, proteomic, and metabolomics profiles (Ricroch *et al.*, 2011; Baker *et al.*, 2006; Catchpole *et al.*, 2005). For example, metabolomic studies in *Solanum tuberosum* have shown that conventional plant breeding produces both intended and unintended effects and that insertion of transgenes can occur with little apparent effect on composition, even when the GM variety produces significant quantities of a new metabolite (e.g., inulin). Indeed, when the introduced gene product (DP2–3 fructans) was removed from the analysis parameters, multivariate statistical analysis showed no significant variation in the metabolic phenotype, including harmful glycoalkaloids, between the GM crop and the progenitor lines, whereas other, conventionally bred cultivars, showed clearly separated metabolic phenotypes (Chassy *et al.*, 2008). Similar results have been observed at the proteome level for other plant species.

It should not be overlooked, however, that in most plant-breeding programs, successive rounds of planting and selection are used to cull out events with obvious and undesirable phenotypes and select plants with unchanged/superior agronomic and phenotypic traits. Regardless of the method of breeding applied to select genetic changes, the candidate plants that are advanced for potential distribution and planting should closely resemble their parental lines – with the sole exception of the intended modification. It also appears that environmental and cultural conditions have more impact on plant composition than breeding and selection programs (Ricroch *et al.*, 2011). Transcriptomic and metabolomic studies in wheat and potatoes, respectively, show greater variation within and between conventionally bred cultivars and even growth locations than between GM and parental variety except for the intended change. To reinforce this observation, differences within lines between sites were generally greater than differences between lines at the same site for both.

However, transcriptomics may be of limited value because assessing potential effects of gene expression on metabolic or phenotypic traits, since so far, in understanding of biological networks is limited and prevents any valid predictions. It is better to directly measure the outcome of genotype–environment interactions instead of trying to predict potential side effects. Metabolomics is a more valid assessment system. These applications follow a two-tiered approach: they can be used for sample discrimination and classification (e.g., for GM comparator analysis) or they can be used for biochemical and mechanistic studies. These tools can be employed to understand which parts of larger biochemical networks respond to genetic modification. Unbiased and comprehensive assessments of potential and immediate risks should, therefore, focus solely on proteins and metabolite analyses, accompanied by necessary developments in validation, statistical assessments, and databases. Where compositional differences are suggested by fingerprinting studies of GM crops, the comparative assessment process, using validated and quantitative compositional analysis methods, can be guided by the fingerprinting results to reach a more informed understanding of the fingerprint results in order to determine whether additional safety assessments are needed.

It is well recognized that absolute safety is not an achievable goal in any human endeavor, and this is relevant with respect to food and feed. The safe use of food or feed has typically been established either through experience based on its common use or by application of generally recognized scientific assessment procedures. Starting in the 1990s, novel (especially GM) food and feed crops have been held to the standard that they should be as safe as an appropriate counterpart with a history of safe use. Based on this with respect to

potential risks to human health, the consensus of scientific opinion and evidence is that biotechnology-derived foods and feeds present no new or unusual dangers to the environment or human health FAO/WHO, OECD, Seven Academies Report, French Medical Association, Royal Society of London, NRC, and Society of Toxicology).

In 2001 and 2011, the European Commission released two reports that cover 25 years of research on GM crops or food on human health or the environment: (EU Commission Report, 2011) 'A decade of EU-funded GMO research (2001–2010)' and 'EC-Sponsored research on the safety of GM organisms (1985–2000) (EU Commission Report, 2001).' Indeed, they concluded that the use of more precise technology and the greater regulatory scrutiny probably make them even safer than conventional plants and foods. The more recent was a compendium of 50 research projects on the safety of GMOs over the past decade. The Commission funded research from 130 research projects involving 500 independent research groups over 25 years, concluding that "There is, as of today, no scientific evidence associating GMOs with higher risks for the environment or for food and feed safety than conventional plants and organisms." A declaration signed by more than 3500 scientists, including 25 Nobel Laureates, reiterates this position.

The medical community has also supported the introduction of biotechnology-derived plants and foods. The American Medical Association states, "it is the policy of the AMA to endorse or implement programs that will convince the public and government officials that genetic manipulation is not inherently hazardous and that the health and economic benefits of recombinant DNA technology greatly exceed any risk posed to society." Although France has been among the most skeptical countries about this technology, the French Academy of Medicine report, Les plantes génétiquement modifiées "Genetically Modified Plants" (ADSF, 2003), called for an end to the European moratorium on GM crops as there was no demonstrated concern from a human health or environmental impact perspective. These crops have been approved for import and sale in the dozens of countries and for growth as crops in more than 30 countries. For example, Bt maize, herbicide-tolerant soybeans, and herbicide-tolerant canola, among others, have been approved for import into the EU and Japan.

The main principles of the international consensus approach are listed below. They serve to illustrate the variety of principles that have been at the center of the discussions and that are continuously being updated:

Substantial equivalence – this is the guiding principle for the safety assessment. In short, substantial equivalence involves the process of comparing of the GM product to a conventional counterpart with a history of safe use. Such a comparison commonly includes agronomic performance, phenotype, expression of transgenes and composition (macro- and micronutrients), and identifies the similarities and differences between the GM product and the conventional counterpart. Based on the differences identified, further investigations may be carried out to assess the safety of these differences. These assessments include any protein(s) that is produced from the inserted DNA. Reports have demonstrated that GM crops are often more closely related to the isogenic parental strain used in their development than to other members of the same genus and species.

Potential gene transfer – where there is a possibility that selective advantage may be given to an undesirable trait from a food safety or environmental impact perspective; this should be assessed, for example, in the highly unlikely event of a gene coding for a plant-made pharmaceutical transferred to commodity to corn. Where there is a possibility that the introduced gene(s) may be transferred to other crops, the potential environmental impact of the introduced gene and any conferred trait must be assessed.

Potential allergenicity – as most food allergens are proteins, the potential allergenicity of newly expressed proteins in food must be considered. A decision tree approach introduced by International Life Science Institute (ILSI)/International Food Biotechnology Council (IFBC) in 1996 has become internationally acknowledged and updated by Codex (FAO/WHO, 2002). Allergy safety assessments use a panel of characteristics to evaluate novel proteins for allergenic potential. The starting point for this approach is the known allergenic properties of the source organism for the genes. Other recurrent items in this approach are structural similarities between the introduced protein and allergenic proteins, digestibility of the newly introduced protein(s), and eventually if needed, sera-binding tests with either the introduced protein or the biotechnology-derived product. If a novel food protein is not similar to allergens and is not derived from allergenic protein families, it is unlikely to provoke allergy. Moreover, if a protein is degraded in simulated gastric fluid, is small in size (e.g., < 10 kDa), and is not glycosylated, the likelihood that it will be an allergen is also unlikely (Lehrer and Bannon, 2005; Sánchez-Monge and Salcedo, 2005). There are many factors that may elicit food protein allergy, including extrinsic factors such as food use and processing; however, this is not well understood and is a continuing topic of research and discussion. It is important to note that many proteins possess one or more of the properties characteristic of an allergen, and yet they do not cause allergy. The likelihood that a novel biotechnology-derived protein will be an allergen is very low for proteins without sequence similarity and physical properties comparable to known allergens. From a safety perspective, the risk of allergy due to introduction of a novel protein into a crop remains low, regardless of whether proteins are introduced through conventional crop breeding or modern biotechnology.

Potential toxicity – some proteins are known to be toxic, such as enterotoxins from pathogenic bacteria and lectins from plants. Commonly employed tests for toxicity include bioinformatic comparisons of amino acid sequences of any newly expressed protein(s) with the amino acid sequences of known toxins with those of introduced proteins, as well as rodent toxicity tests with acute administration of the proteins. Currently, appropriate toxicity studies are typically needed for the introduced protein in GM crops. The assessment often includes studies such as conducting a bioinformatic comparison of the new protein's amino acid sequence with a database of all publicly available protein sequences (e.g., protease inhibitors and lectins) and testing the newly introduced protein's stability to heat or processing and to degradation in suitably representative gastric and intestinal model systems. Appropriate toxicity studies may be needed in cases where the protein

present in the food is dissimilar to proteins that have previously been consumed safely in food. Such studies should also take into account the biological function of the protein in the plant, when known. In addition to purified proteins, whole grain from GM crops has been tested in animals, commonly in subchronic (90 days) rodent studies.

Unintended effects – besides the intended effects of the modification, interactions of the inserted DNA sequence with the plant genome are possible sources of unintended effects. Another source might be the introduced trait unexpectedly altering plant metabolism. Unintended effects can be both predicted and unpredicted. For example, variations in intermediates and endpoints in metabolic pathways that are the subject of modification while undesirable are predictable and while switch on of unknown endogenous genes through random insertion in control regions is both unintended and unpredictable. The process of product development that selects a single commercial product from hundreds to thousands of initial transformation events eliminates the vast majority of situations that might have resulted in unintended changes. The selected commercial product candidate event undergoes additional detailed phenotypic, agronomic, morphological, and compositional analyses to further screen for such effects.

Long-term effects – it is acknowledged that the premarket safety assessment should be rigorous to exclude potentially adverse effects of consumption of foods or feeds derived from GM crops. Nevertheless, some have insisted that such foods should also be monitored for long-term effects by postmarket surveillance. The cost to benefit of such surveillance is severely skewed toward the cost side. This observation is predicated on a number of facts. In the first place, no international consensus exists as to whether such surveillance studies are technically possible without a testable hypothesis in order to provide meaningful information regarding safety. Second, any GM crop with a testable safety concern will not pass regulatory review as the deregulation process is so thorough. In fact, there is probably a greater probability of a non-GM crop slipping through as they are not subject to any premarket surveillance. Finally, the practical feasibility of implementing such a process is also not trivial. One potential method would be the use of measurable biomarkers; however, these would need to be determined for all foods and feeds, irrespective of the source and the question of reasonable economic burden arising. Most probably, the marketplace would not support such a requirement as the value gained would not be considered a counter to the costs.

Besides the international organizations, such as the FAO/WHO, OECD, ILSI, and the IFBC, other organizations have also formulated their views and recommendations on the oversight of GM crops.

It can be expected that bioengineering the increase of a certain metabolite or introducing novel pathways may have side effects on the overall metabolic network by redirecting some of the metabolic fluxes and by unforeseen metabolic reactions due to potential lack of substrate specificity of the introduced enzymes. However, compared with the plethora of allelic interactions that result from conventional crosses and classical breeding procedures, such directed and limited molecular interventions cannot be regarded as a less safe intervention per se and hence any considerations of extended safety assessments would need to be forced onto varieties that are derived by either technology, breeding, or molecular techniques. Still, GM plants with improved stress responses are very likely to adopt such desired performances by drastically altering their metabolite compositions, hence potentially falling outside the compositional ranges set by classical varieties. For example, the introduction or overexpression of suite of transcription factors might trigger many different events, some of which could potentially lead to unwanted side effects, such as increased levels of antinutrients or toxicants. Hence, the extent of such changes needs to be determined by appropriate analytical tools and useful statistical estimates for a range of genotype–environment interactions.

Targeted Analysis

The term 'safety' itself is not a purely scientific and objective measure but is clearly defined by society, risk tolerance, and policy settings. Industrialized nations with slow or negative population growths tend to be very risk adverse and thus emphasize potential, but not actual, dangers of novel technologies or developments, whereas regions with severe food shortages, high population growths, or high variability of environmental stress factors clearly and rightfully may emphasize current needs and may demand rapid improvements of the available plant germplasm. Consequently, it cannot be anticipated that there are global, universally applicable risk thresholds that are set independent from societal and political environments. Instead, safety assessments should distinguish between immediate and potential implications of altered food compositions. Immediate requirements for improved ('novel') foods are based on comparisons with its closest comparator lines with respect to phenotypic characteristics (e.g., taste and texture), macro- and micronutrients, and antinutrients and toxicants, in addition to agronomic traits such as yield. The safety of these compositional values is based on historic experience and should be tightly regulated and critically assessed if a given single food provides the overwhelming nutritional basis for the majority of a population in a specific region. Fortunately, there are many validated and approved target methods available to test for the concentrations of nutrients and known toxicants so that any novel food, or any newly bred variety, can easily be tested for its compositional quality at comparatively low costs. To prevent malnutrition or intoxications, safety assessments on these target compounds should be made mandatory for any newly introduced variety. The OECD has developed international consensus documents on the suite of metabolites that should be analyzed for specific crops (OECD, 2003). By selecting the nutritionally and antinutritionally relevant compounds, this strategy provides considerable protection against unintentional changes that might affect human or livestock health and well-being.

However, in the OECD countries, public concerns about potential side effects in novel foods go beyond such historically established baselines of 'safe' food usage. In principle, it cannot be excluded that allelic interactions or molecular tools may generate allergenic proteins or potentially harmful concentrations of toxic metabolites, and examples of both are published in the literature at least for classically bred plants. The plasticity of plant metabolism is astounding, giving rise to

more than 200 000 different known plant metabolites. Only a very small number of these metabolites have ever been tested for antinutrient or toxic activity. Structural properties of proteins or metabolites alone cannot establish their potential for adverse effects or safe minimal concentrations of these. Hence, additional techniques are sought that may be used to analyze metabolic and protein compositions in a comprehensive manner. Over the past decade, such techniques have been developed and are increasingly used not only in research and development but also in assessing novel foods and GM plants. Although in principle even DNA or mRNA products may be investigated for differential expression in novel foods compared with previously introduced lines, there is no indication that RNA themselves may play any role in nutrition or cause potential toxic effects, more likely due to their direct digestibility and lack of potential harmful structural modifications or catalytic activities. In research, studies aim at linking the potential effects of gene expression on metabolic or phenotypic traits, but so far, understanding of biological networks is limited and prevents any valid predictions. Consequently, it is more straightforward to directly measure the outcome of genotype–environment interactions instead of trying to predict potential side effects. Unbiased and comprehensive assessments of potential and immediate risks should, therefore, focus solely on proteins and metabolite analyses, accompanied by necessary developments in validation, statistical assessments, and databases.

Approaches to identify unintended effects

In a similar manner to 'safety,' the term 'unintended effects' is equally ill defined and subject to change corresponding to societal and political reassessments. In metabolic bioengineering, one may assume the intended effect only to be altered levels of a target metabolite, but in reality, other metabolites closely involved in biosynthetic routes will also be affected. In this sense, such effects may be regarded unintended but surely not unexpected. On a case-by-case basis, a list of potentially affected metabolic by-products may complement the target studies on known nutrients, antinutrients, and toxicants. Such approach combining a larger set of predefined analytical targets is called 'metabolite profiling,' because it serves as a general overview of important compounds and relevant biochemical pathways. However, due to the high plasticity of plant metabolism, further unintended and unexpected effects cannot be excluded a priori, especially if the output trait of the novel plant lines were geared toward improved agronomic traits, such as stress resistance. If political and societal decisions are made that risk assessments of novel foods should extend to potentially new molecules, under the precautionary principle, then studies could comprise tests if there are (1) any totally novel compounds that were synthesized by potentially novel biochemical routes and (2) compounds that are beyond the upper or lower range of a set of comparable, already marketed plant lines under a set of environmental conditions.

It is important not solely to compare, for example, a stress-resistant plant line to comparator lines under normal growth conditions but also under stress conditions because the stress-resistant plant line may already be preadapted and hence metabolically different to the comparator lines before even the stress situation (drought, cold, salinity, etc.) takes place. If safety is defined by historic experience of safe use, then this experience surely includes food that was derived from stress-grown plants, and hence the ranges of metabolic compositions must include these situations. It would be far too demanding if any novel food would need to pass a suite of growth trials under different environmental conditions. Instead, unintended and unexpected effects could be assessed by comparing the compositions of novel foods in relation to publicly available, untargeted (unbiased) databases. Such comprehensive and untargeted compositional analysis that would necessarily screen for unidentified structures is called 'metabolomics.' In a similar manner, proteomic databases could be used to assess the range of naturally occurring proteins and protein abundances. A range of techniques can be used for comprehensive metabolomics, and equally broad are possibilities to use proteomic methods. Efforts are underway in both areas to standardize the reporting structure of such –omics – data and to recommend current best practices. These are important steps to harmonize workflows and to enable queries of the proteomes or metabolomes of novel foods against databases in order to find unintended and unexpected events. So far, no public repositories on baseline metabolomes and proteomes of crops are available, and it would demand significant budgets to establish such databases. However, in principle, technologies are available and their proper use and data storage can be established, standardized, validated, and monitored. Reasonably, databases for staple crops would need to be established first before moving to feeds and foods with lesser use. It is depending on societal and political decisions if funds are made available to establish and curate such databases based on risk–cost–benefit discussions.

Analytical methods for detection of unintended effects

As stated above, the most reasonable approach to look for unintended effects is to quantify the amounts of known and biologically relevant macro- and micronutrients, including vitamins, antinutrients, allergens, and toxic compounds. Analyses must be carried out using validated techniques, at best in certified laboratories, that perform at-cost assessments of the compositional profiles. Even when just two lines are compared, severe statistical constraints must be obeyed, as pointed out in a thorough statistical paper by Hothorn and Oberdoerfer (2006). For evaluating the relevance of compositional differences in novel foods, which may include GM crops, it is important to compare nutrient levels with the range of concentrations that can be observed in other cultivars or varieties and not only in the direct parental lines. The more the compounds are screened and the more the individual samples are analyzed, the more likely it is that a number of levels turn out to be 'significantly different' from the parental lines. This fact is based on simple considerations of statistical probabilities and has nothing to do with nutritional relevance. It is, therefore, sensible to test if the levels of target compounds are out of range of corresponding counterparts that are regarded as 'safe' for human or livestock consumption. In this respect, the ILSI database may be regarded as important cornerstone to emphasize the breadth of natural variability, especially with respect to genotype–environment interactions. Owing to differences in growing conditions and environmental stress

factors, nutritional values cannot be standardized in a global manner. For certain compounds like glycoalkaloids, upper levels have been defined by the OECD as safeguard against unwanted side effects of either breeding or biotechnology efforts. It might be useful to define further concentration limits for further target compounds, both on upper and lower limits, based on physiological and medical evidence. If these ranges would only be given by agricultural practices, it might otherwise appear that a certain (classic) variety under very specific stress conditions would result in a compositional profile that was vastly different from usual compound levels. Hence, comparisons of concentrations against nutritional databases should also consider frequency distributions of normally reported levels, and not take outliers as out-of-range limits.

As stated above, there is no reason to embark on gene expression or microarray analyses for food safety assessments. These techniques are surely useful for basic science, plant research, and crop development but yet lack to prove that useful predictions of antinutritional or toxic effects can be made that would not be picked up in (more cost efficient) targeted or nontargeted metabolic or protein profiles.

Proteomics – Proteomics and protein profiling have been used for more than 30 years as research tool for comprehensive analyses of protein abundance and protein identifications. In a similar manner to metabolic compounds, there are proteins that are known to cause allergenic or other toxic effects and thus should be monitored in principle with highly selective and sensitive techniques, such as western blots or 'mass westerns,' which employ liquid chromatography (LC) and triple quadrupole mass spectrometry (MS) for specific fragments and mass transitions of target proteins. Unfortunately, there is no prediction tool that would allow an unbiased calculation of the likelihood that any given protein, or a specific protein post-translational modification (e.g., glycosylation, phosphorylation, or any of the other 200 known modifications), would raise safety concerns with respect to potential toxic or allergenic effects. If nontarget 'fishing' for novel proteins is sought, which may be used as a preliminary indication of potential concerns, validation and statistical strategies have to be taken that are highly similar to targeted or nontargeted metabolite analyses. First, the proteomic techniques have to prove that they can be used in a robust and reliable manner, giving precise quantification results for a wide range of proteins. In principle, two methods can be applied for the nontargeted comparisons of relative protein abundances: either classical two-dimensional gel electrophoresis (2D gels) using visual staining for detection or chromatography-based separations followed by mass spectrometry detection and quantification (LC/MS). 2D gels can be used today at comparatively low costs and high precision; however, integral membrane lipophilic proteins and proteins of either very high or very low masses are usually not detectable by this technique. In addition, spot detection, gel alignments, and automated quantifications have to be shown to work reliably for standard food and feed crops, before proteomic databases can be set up to define again out-of-range limits of proteins. Recently, Ruebelt and others published a series of papers (Ruebelt *et al.*, 2006a,b,c) demonstrating 2D gel proteomics of *Arabidopsis thaliana* seed samples that the method itself can be worked out to reproducibly detect and quantify spots, but that there was a wide range of protein abundances when 12 different *Arabidopsis* varieties were compared, covering the abundance range of GM *Arabidopsis* lines. A similarly thorough study on potato varieties and GM lines concluded that proteome dissimilarities between different individual cultivar lines were far larger than comparing a GM line to its progenitor (Lehesranta *et al.*, 2005). In principle, 2D gel proteomics may be used if efforts are made to ensure quality controls and a high enough sample throughput to cope with the statistical challenges.

Another approach in proteomics is to utilize LC/MS on fractionated or partly fractionated proteome samples, for example, by using online cation exchange fractionation steps before LC/MS separation of trypsin-digested proteomes. Such approaches can be used with or without labeling with stable isotope intermediates that are often employed in order to enhance the precision of quantification results. No reports have yet been published on plant proteomes with the same diligence on precision and range assessments as with the 2D gel approach. In principle, proteome fractionation with subsequent LC/MS quantifications may work but is still plagued by some fundamental challenges called ion suppression and retention time alignments. For either of the two general approaches on proteome quantifications, laboratories have to prove that they can perform protein quantifications in a high-throughput manner using quality control charts and precision analyses as minimum quality checks to be able to populate range assessments of crop proteome databases.

Metabolomics – Products of metabolism present a very important part for assessing potential unintended effects, due to the lack of substrate specificity of many enzymes and the resulting large metabolic plasticity in plants. A broad-scale analysis of metabolites can, therefore, provide three aspects to evaluating the similarity, and hence unlikelihood of safety concerns, when comparing novel foods to comparator lines. First, novel compounds may be detected that are absent in any of the classically bred ('safe') cultivars. Novel metabolites themselves cannot be regarded a safety concern because mammalian metabolism is ideally adapted to cope with a wide range of compounds. However, it would be important to associate chemical structures or characterize the substance classes in order to unravel potential similarities to known toxicants or antinutrients. Second, known and structurally uncharacterized metabolites may be present out of range compared with the levels found in metabolomic databases or at least compared with the concentrations detected in a given range assessment study using multiple comparator lines. In a similar manner to presence or absence of novel compounds, the sheer finding that certain compounds are at higher or lower concentrations compared with similar plant lines does not substantiate safety concerns. Nevertheless, it would be important to evaluate the magnitude of differences, the number of different compounds, and their chemical structures to found the basis of the assessment of potential risks. Third, any test on the similarity of individual compound levels might obscure the overall dissimilarity of metabolic patterns. Each individual compound could in principle be barely found to be within range, but the total composition might still be quite different, with many compounds highly upregulated and many others with downregulated levels.

Metabolomic techniques have advanced during the past 5 years. Four different areas of metabolite analysis can be

distinguished: (1) metabolite target analysis, as outlined above; (2) metabolite profiling, aiming at a limited number of compounds or a few selected pathways, using a single specific analytical technique; (3) metabolomics, which necessitates use of a number of different techniques to (ideally) identify and quantify all metabolites present in a given biological situation; and (4) metabolite fingerprinting, which globally assesses the complement (pattern) of metabolites without necessarily identifying individual compounds. The latter approach is usually the most cost-effective method and provides a first broad overview and pattern analysis of overall similarity. Particularly for nuclear magnetic resonance studies (NMR), instrumental parameters can be controlled in such a way that many samples can be analyzed with high precision of quantification results. Although resolution and sensitivity of classic NMR analyses prevent the unambiguous identification of low abundant metabolites, a number of compounds can still be associated to proton NMR shifts. An NMR study on GM wheat revealed surprisingly high differences when lines were grown on two different locations within the United Kingdom, providing evidence for the importance of gene–environment interactions in substantial equivalence studies. Another study including 40 potato GM lines derived from two progenitor varieties further confirmed that the largest differences were detected between the varieties but not between GM and non-GM lines in general (Defernez *et al.*, 2004). Differences associated specifically for individual GM lines were generally within the range given by the cultivars except for intended effects (e.g., in polyamine pathways) or for phenotypically severely hampered lines.

If newer correlation spectroscopy methods are used, particularly total correlation spectroscopy and selective total correlation spectroscopy, NMR metabolite fingerprints may reveal dozens of metabolites in highly quantitative manner (Cloarec *et al.*, 2005). So far, however, no study on crop metabolite fingerprinting has been performed utilizing two-dimensional NMR techniques. Alternatively, various techniques in mass spectrometry-based metabolomics can be applied to study metabolic compositions. In a field trial on transgenic potato lines overexpressing two genes for engineering high fructan contents, Catchpole from the Fiehn laboratory and collaborators from the University of Aberystwyth, UK (2005) suggested a metabolomic hierarchy for testing substantial equivalence. First, overall similarity was assessed by metabolite fingerprinting, which was carried out by direct infusion mass spectrometry. Differences between mass spectra of six GM lines to six non-GM comparator potato lines could be associated to fructan-derived signals that were confirmed by metabolic profiling using hydrophilic interaction chromatography–mass spectrometry. However, even after removing the 15 most abundant fructan ions, differences between GM and non-GM lines remained for low molecular masses. Hence, the investigation was extended to gas chromatography–mass spectrometry, a technique specifically powerful for metabolites below 500 Da. It could be shown that residual differences were related to fructans with a degree of polymerization of two and three, without any further compound detected above out-of-range limits that were defined by the six comparator cultivars. Removing the DP2–3 fructans resulted in a total collapse of GM metabolic phenotypes with the Desiree progenitor lines in multivariate statistics plots, whereas the other classically bred cultivars still showed clearly separated metabolic phenotypes. Finally, metabolite fingerprinting and metabolite profiling approaches were complemented by metabolite target analysis for glycoalkaloid contents (Zywicki *et al.*, 2005) for both potato peel and potato flesh concentrations. It was shown using two different LC-MS/MS techniques that concentrations of these harmful compounds also remained within the limits given by the comparator lines, hence proving that no safety concerns could be deduced from this comprehensive metabolomic study.

In addition to univariate and multivariate statistical analyses used in this potato study, the Fiehn lab at UC Davis has developed a metabolite database that combines metabolomic data acquisition readouts with the underlying experimental design metadata (SetupX and BinBase, Fiehn *et al.*, 2005). This database enables capturing even structurally unidentified compounds in order to assess the variability of these metabolites across species and experiments. As part of these efforts, Fiehn *et al.* have developed new distance metrics that robustly recognize coregulation of pairs of metabolites that can then be visualized and compared by network graphs using Bayesian likelihood models. Ultimately, changes in these networks can be related back to interactions with the underlying biochemical pathways, protein–protein interactions, and genetic networks that can be used to understand the relationship between the different cellular components in GM and comparator plants.

Conclusions

It remains mandatory to monitor novel foods and feed by metabolite target analyses for nutritional value and antinutrient and toxicant levels. In addition to range levels that are recommended for these compounds based on health considerations, it is recommended to extend and establish metabolic composition databases that enable assessing natural variability in crops that result from gene–environment interactions. In addition to such direct approaches, nontarget methods have been established for both protein and metabolite compositions that may enable detecting specific differences between novel plant lines and a variety of comparator lines, if natural variability and quality control measures are adequately addressed. Profiling gene expression levels is regarded unnecessary for safety evaluations at the current state because no accurate predictions can be made from such array studies with respect to potentially harmful allergenic proteins or levels of novel metabolites. It is recommended that profiling database for crops are established spanning different environmental conditions in order to enable baseline assessments to which profiles of metabolites and proteins in novel foods may be compared, irrespective of these being generated using molecular biology techniques or otherwise.

The consensus of scientific opinion and evidence from more than 600 studies worldwide is that biotechnology-derived foods and feeds present no new or unusual dangers to the environment or human health (American Medical Association, WHO, OECD, Seven Academies Report, Royal Society of London, NRC, and Society of Toxicology). Worldwide, tens

of millions of livestock, including chickens, pigs, and cows, are fed with GM soybeans mostly imported from Brazil and Argentina. With the current regulatory environment and monitoring by veterinary authorities, any health impacts related to the consumption of GM crops should be have been reported if there were any safety concerns. This has not been the case for almost two decades since biotech products were first approved by the EU. An estimated 2 trillion meals containing GM ingredients have been eaten around the world over the past 13 years without a single substantiated case of ill health.

The most that can be expected of any oversight regimen is that foods developed using all methods should receive the same level of evaluation both with regard to impact on the environment and safety to the consumer. Millions of people have already eaten the products of genetic engineering and no adverse effects have been demonstrated. Both current science and long-term experience support the repeated conclusions of learned bodies that it should be the product, not the process by which it is developed, that should be evaluated for both risk and benefit. Scientists are confident that if one abandons the scientific method in judging the safety of the food supply and the impact on the environment, one will slow or destroy the advances that will reduce the use of unsafe chemicals and less safe agricultural practices in this country and will limit the potential for improved nutrition and quality that promise to increase food security and enhance sustainability worldwide.

Regulatory Conventions and Institutions that Govern Global Agricultural Trade

C Zepeda, US Department of Agriculture, Fort Collins, CO, USA

Published by Elsevier Inc.

Glossary

Codex Alimentarius (Codex) International food standards, guidelines, and codes of practice that contribute to the safety, quality, and fairness of this international food trade.

International Plant Protection Convention (IPPC) An international agreement on plant health that aims to protect cultivated and wild plants by preventing the introduction and spread of pests.

Phytosanitary Measure (Measure) A legislation, regulation, or official procedure to prevent the introduction and/or spread of quarantine pests, or to limit the economic impact of regulated nonquarantine pests. (Source: ISPM 5).

World Organization for Animal Health (OIE) The intergovernmental organization that is recognized by the WTO and is responsible for improving animal health worldwide.

World Trade Organization (WTO) The only global international organization dealing with the rules of trade between nations. At its heart are the WTO agreements, which are negotiated and signed by the bulk of the world's trading nations and are ratified in their parliaments. The goal is to help producers of goods and services, exporters, and importers conduct their business.

The Agreement on the Application of Sanitary and Phytosanitary Measures

The Uruguay Round of Multilateral Trade Negotiations of the General Agreement on Tariffs and Trade (GATT) concluded in 1994, after 7.5 years of negotiations, with the signature of the Final Act, in Marrakesh, Morocco on 15 April 1994. This became known as 'the GATT of 1994' and led to the creation of the World Trade Organization (WTO) on 1 January 1995 (WTO, 2013). Among the agreements that were included in the treaty that established the WTO, is the Agreement on the Application of Sanitary and Phytosanitary Measures (SPS Agreement), which sets out the basic rules for the protection of public, animal, and plant health during international trade (WTO, 1995).

The SPS Agreement has changed the way in which trade decisions related to agricultural products are made. Its main intent is to facilitate trade and avoid the use of sanitary and phytosanitary measures as unjustified barriers to trade. The Agreement dictates that all measures must be scientifically based and not unnecessarily restrictive, while recognizing the right of countries to protect human, animal, or plant life or health.

The Three Sisters

The SPS Agreement demands that all sanitary and phytosanitary measures should be science-based and nondiscriminatory, and encourages the application of international standards. The WTO relies on three international organizations to develop standards for animal health, plant health, and food safety. These organizations, colloquially known as the 'three sisters' are: the World Organization for Animal Health (OIE, based on its former name 'Office International des Epizooties'), the International Plant Protection Convention (IPPC) and Codex Alimentarius (Codex).

World Organization for Animal Health

Established in 1924 and headquartered in Paris, the OIE is the organization responsible for setting international standards for animal health. The World Assembly of Delegates, comprised by the 178 Delegates of all member countries, is the highest authority of the OIE and meets at least once a year (OIE, 2013). The objectives of the OIE are to:

- Ensure transparency in the global animal disease situation;
- Collect, analyze, and disseminate veterinary scientific information;
- Encourage international solidarity in the control of animal diseases;
- Safeguard world trade by publishing health standards for international trade in animals and animal products;
- Improve the legal framework and resources of national Veterinary Services;
- Provide a better guarantee of food of animal origin and to promote animal welfare through a science-based approach.

The standards are laid out in the Terrestrial Animal Health Code, the Aquatic Animal health Code and their corresponding Manuals for Diagnostic Tests and Vaccines which are updated annually (OIE; 2012a,b,c).

International Plant Protection Convention

Established in 1952, the IPPC is an international plant health agreement that aims to protect cultivated and wild plants by preventing the introduction and spread of pests. The IPPC has 178 signatories. The Commission on Phytosanitary Measures is the governing body of the IPPC, providing guidance to the IPPC Secretariat on strategic direction, cooperation, financial, and operational management. The Secretariat is provided by the Food and Agriculture Organization of the United Nations with headquarters in Rome.

The IPPC coordinates with relevant international, regional, and national organizations to:

- Protect farmers from economically devastating pest and disease outbreaks,
- Protect the environment from loss of species diversity,
- Protect ecosystems from loss of viability and function as a result of pest invasions,
- Protect industries and consumers from the costs of pest control or eradication.

International standards developed by the IPPC primarily cover international trade of plant and plant products, but also include, among other topics, plant pests and their vectors, research materials and germplasm.

Codex Alimentarius

Established jointly by FAO and WHO in 1963, the Codex is the organization responsible for developing international standards for food safety. There are 186 Codex members that collectively cover 99% of the world's population (FAO/WHO, 2013).

Codex standards deal, among other things, with characteristics of food products, maximum residue limits, food additives, and labeling. In addition, Codex Codes of Practice deal with practices related to hygiene, production, processing, manufacturing, transport, and storage. Finally, Codex guidelines outline principles to define policy and provide guidance in the interpretation of the provisions of the Codex general standards (FAO/WHO, 2006). The standards are compiled and published in the Codex Alimentarius.

Key Provisions

The SPS agreement lays out five key provisions: harmonization, equivalence, risk assessment, regionalization, and transparency.

Harmonization

Harmonization is the establishment, recognition, and application of common sanitary and phytosanitary measures. The SPS agreement encourages countries to base their measures on international standards developed by the relevant international organizations. Countries may apply SPS measures that are more stringent than the international standards as long as they are scientifically justified and based on a risk assessment.

Although membership of the reference international organizations is not mandatory, the SPS Agreement has led to an increase in the number of countries belonging to, and actively participating in, these organizations. The development of international standards requires significant scientific input from specialists in a wide array of technical fields.

Equivalence

The concept of equivalence implies the consideration and acceptance of different SPS measures as long as they achieve similar results. Exporting countries have to justify the scientific basis of the procedures used and objectively demonstrate that they achieve the level of protection required by the importing country. Member countries are encouraged to develop bilateral or multilateral equivalence agreements.

The main tenet of equivalence is the emphasis on results rather than methods or approaches. This allows for flexibility in the organization of official animal, plant, and food safety services and allows for countries to direct their efforts on key areas, according to resources and priorities.

The three international standard setting organizations encourage their member countries to adopt the concept of equivalence. For example, the OIE Code contains a chapter related to the SPS agreement (OIE, 2012a) that discusses principles and outlines a step-wise process to be used in determining equivalence. Furthermore, the chapter emphasizes that equivalence may apply to specific measures (e.g., comparison of different diagnostic procedures) or on a system-wide basis (e.g., equivalence of surveillance systems). There is a need to develop and establish methods to recognize equivalency by developing scientific procedures enabling an unbiased comparison of different approaches.

Risk Assessment

The SPS Agreement defines risk assessment as the "evaluation of the likelihood of entry, establishment, or spread of a pest or disease within the territory of an importing member according to the sanitary or phytosanitary measures which might be applied, and of the associated potential biological and economic consequences; or the evaluation of the potential for adverse effects on human or animal health arising from the presence of additives, contaminants, toxins or disease-causing organisms in food, beverages or feedstuffs." (WTO, 1995).

The article on harmonization states that in the event that an international standard does not exist or does not meet the level of protection required, a country has the right to establish SPS measures based on a scientifically sound risk assessment. The OIE Code contains a section on import risk analysis (OIE, 2012a). Similarly, the IPPC has produced a framework for pest risk analysis IPPC (2007) and a section of Codex' procedural manual (FAO/WHO, 2007) outlines the process. It is interesting to note that the SPS Agreement refers to risk assessment, while the OIE and IPPC use the term risk analysis, within which risk assessment is one of the components of the process.

A common perception is that if an importing country applies the risk-mitigation recommendations set by the relevant international organizations, a risk analysis is not necessary. While it is true that an in-depth risk analysis may not be necessary, the establishment of import requirements involves at least a partial application of the risk analysis process. Part of the complexity in developing import requirements is that multiple hazards can be identified for each commodity. However, the recommendations for animal and plant health are based on an individual disease or pest basis. The question then becomes how to merge the recommendations with the hazards that were identified? Risk analysis in its simplest form provides a framework to establish a link between the hazards identified for the specific commodity, the sanitary status of the exporting and importing countries and international

recommendations. There is a need to promote a better understanding among decision-makers of the concept of risk analysis, its application and limitations. Although each risk assessment is likely to be different, there are common methods, tools and techniques that can be used.

Training is essential to develop the capability to perform rigorous risk assessments. A survey conducted among OIE member countries showed that the majority of countries still require training in risk analysis methods despite the fact that the same survey found that most countries had already received some type of training in this area (Zepeda, 2002). In the field of animal health, the OIE Collaborating Center for Animal Disease Surveillance Systems and Risk Analysis developed a series of short training courses on epidemiology and risk analysis and has organized and conducted several training sessions internationally. Similarly, other institutions worldwide are offering short courses on risk analysis. However, there is a lack of formal training opportunities in risk analysis within universities at the graduate or postgraduate levels.

Risk is defined as the probability of occurrence and the magnitude of the consequences (Ahl et al., 1993). A complete risk assessment should include all the relevant steps outlined by the reference organizations; this is a requirement under the dispute settlement process of the WTO. The Canadian salmon dispute was the first animal health case to go through the WTO dispute settlement process. The Appellate Body report reviewing the Canadian salmon dispute established three conditions to assess if a risk analysis can be considered valid. These include (1) identifying the diseases that may be introduced and their associated consequences, (2) evaluation of the likelihood of entry, establishment; and spread of the diseases identified as hazards as well as the biologic and economic consequences; and (3) evaluation of the likelihood of entry, establishment, and spread of the diseases according to the SPS measures that might be applied (WTO, 1998). A more thorough description of the findings of the Panel is given under the dispute settlement section of this article.

Risk management requires comparing the results of the risk assessment with the country's acceptable level of protection (ALOP). The SPS Agreement recognizes that establishing the ALOP is a prerogative of the importing country (WTO, 1995,1998). However, it does not define how to establish the ALOP, although the process by which it is established must be transparent and applied in a nondiscriminatory fashion. The difficulty in defining the ALOP resides not only on developing good quality risk assessments, but also needs to consider economic implications and societal values.

The application of the risk analysis process requires expertise and a multidisciplinary approach. In several developing countries, this expertise does not exist, emphasizing the need for training and establishing mechanisms to enable access to relevant scientific information.

Regionalization

In the past, when a disease agent existed in a country, the entire territory was considered as infected. The SPS Agreement recognizes that it is possible to consider all of a country, part of a country, or all or parts of several countries free from disease/infection based on the epidemiology of the disease and other criteria. This provision is generally known as zoning or regionalization. It is worth noting that both terms are considered synonymous and can be used interchangeably.

Regionalization requires effective surveillance systems and good quality animal and plant health services both at the national and regional level. When determining the status of a country or zone consideration of several factors has been suggested (CFR, 2013):

- Scope of the evaluation being requested,
- Veterinary control and oversight,
- Disease history and vaccination practices,
- Livestock demographics and traceability,
- Epidemiological separation from potential sources of infection,
- Diagnostic laboratory capabilities,
- Surveillance practices,
- Emergency preparedness and response.

Although these eight factors were developed specifically for animal health, the considerations to assess the status of a country or zone for plant health issues are similar. The quality of the official services both at the national and at the regional level plays a crucial role in preventing the reintroduction of disease. Surveillance systems are essential in providing information for the recognition of disease-free zones and to conduct scientifically valid risk assessments.

Different approaches to zoning and regionalization have been adopted:

- Zoning to contain disease outbreaks.
- Zoning of disease-free areas.

Although the same principles are applied, the emphasis is different. From a risk point of view, the application of zoning as a reaction to disease incursion is not the same as the application of zoning as a measure of progress of a disease eradication program. In the first instance, a zone is a way to separate a diseased area in an otherwise disease-free country; in the second, the zone is a way to secure a free area in an otherwise infected country.

A zone that is defined on grounds of infection, after an outbreak, is less stable. Producers within the zone have to abide by a series of measures that are imposed on them and will affect their normal activities. Movement controls, although strict, may not be efficient and there may be incentives for producers to circumvent them. The disease may spread and the zone's boundaries may need to be modified accordingly. A certain amount of time is needed to achieve stability and demonstrate that the disease is effectively contained within the zone.

A zone that achieves disease eradication and claims freedom is much more stable, it reached that status through a structured disease control program, animal movement controls, active surveillance and producer participation. Furthermore, usually the rest of the country is also under a disease control and eradication program, reducing the risk of reintroduction.

Compartmentalization

A new concept for the management of animal health is compartmentalization, which is a procedure to define animal

populations of different animal health status based on management and biosecurity. Compartments are defined on the basis of the functional relationships of the units within them. The concept of compartmentalization is better suited to vertically integrated production systems such as the poultry or swine industries, where all the units within the system are under the same management and biosecurity practices.

Compartmentalization can be applied in situations where different production systems coexist such as commercial and subsistence farming. In general, commercial farms are in a better position to control and eradicate disease and maintain their status. Having reached this status it is possible through appropriate biosecurity measures to effectively avoid the reintroduction of disease from the affected compartment.

As is the case with regionalization, credibility is the basis for recognition of the status of the compartment. Credibility can only be achieved by effective surveillance, movement controls, producer participation, and most importantly, transparency.

Regionalization has allowed resources to be directed more efficiently by allowing access to export markets from disease-free areas without the need to achieve eradication in the entire territory of a country (Zepeda, 1998). From a scientific perspective, disease freedom cannot be conclusively demonstrated. There is a need for the development of methods to substantiate disease freedom claims that include evidence from structured random surveys as well as nonrandom data sources, such as information from passive surveillance systems. Quantification of the joint probability of detection of all the components of a surveillance system allows reaching a high level of confidence of the absence of disease, higher than any of the components individually (Cannon, 2002; Cameron *et al.*, 2003). There is also a need to include economic considerations in defining the intensity of surveillance and deciding on the optimal combination of surveillance components of a system.

Transparency

The SPS Agreement requires countries to notify the WTO about changes in measures that have an impact in international trade. SPS measures must be published and accessible through an official inquiry point. The transparency provision also includes control and inspection procedures as well as risk assessment. Throughout the process, confidentiality of commercial information is maintained (WTO, 1995). In many countries, the transparency provision has led to review the process of regulation drafting, resulting in more open processes that allow input from all interested parties.

The concept of transparency also applies to reporting of the disease situation in a country. OIE and the IPPC have reporting requirements for their members and the information is made publicly available. Transparency on the sanitary and phytosanitary status is the basis for trust in international trade.

Dispute Settlement

WTO member countries have the right to invoke the dispute settlement procedure; however, bilateral settlements are always encouraged. The OIE has set up a procedure for 'in house' dispute settlement (Chapter 1.3.1, OIE Code) (OIE, 2012a; Vallat and Wilson, 2003). Countries using the dispute settlement procedure must be ready to defend their positions with scientifically valid arguments.

The WTO dispute settlement procedure is a lengthy procedure that can be very costly (WTO, 2003) and often requires legal advice and a continuous presence at WTO's headquarters. Therefore, it is a procedure best suited for issues that imply large amounts of trade. It is possible that developing countries may not be willing to elevate a dispute to this level due to financial constraints, leading to an inequitable application of the rights embedded in the SPS Agreement.

Article 12 of the SPS agreement establishes the creation of the SPS Committee to provide a forum for regular consultations. Further, the article encourages the Committee to facilitate negotiations and discussions between parties involved. The SPS Committee acts as the first forum in which SPS-related disagreements can be discussed once bilateral talks have been exhausted. Often, the fact of raising an issue at the SPS Committee level leads to renewed bilateral discussions resulting in very few disputes needing to go through the entire dispute settlement process. In fact, only three cases related to SPS issues had been through the complete formal WTO dispute settlement procedures.

In all formal disputes, risk assessment has been the central part of the technical and scientific evidence submitted to the expert panel. The Appellate Body reviewing the Canadian/Australian salmon case underscored the importance of submitting complete risk assessments and defined a three-pronged test to assess if a study can qualify as a risk assessment under Article 5 and the definition in annex B. According to the panel, an import risk assessment needs to (WTO, 1998):

1. "Identify the diseases whose entry, establishment or spread a Member wants to prevent within its territory, as well as the potential biological and economic consequences associated with the entry, establishment or spread of these diseases;
2. Evaluate the likelihood of entry, establishment or spread of these diseases, as well as the associated potential biological and economic consequences; and
3. Evaluate the likelihood of entry, establishment or spread of these diseases according to the SPS measures which might be applied."

The Appellate Body report emphasized the importance of a solid scientific basis and the coherence between the risk assessment and the resulting SPS measures that are applied. Evidently, good epidemiology is the basis to satisfy this requirement. The report also distinguished between possibility – instead of likelihood or probability – of disease entry, stressing that the second test requires the evaluation of the likelihood (not mere possibility), without there being a need for this evaluation to be done necessarily in a quantitative way.

Challenges and Opportunities

Regionalization, compartmentalization, and risk assessment allow for trade to occur even if a disease has not been

completely eradicated within a country. This has allowed countries to access export markets that were previously inaccessible due to the presence of specific diseases, and, in turn, has led to increased transparency, as countries are more willing to share information on the sanitary and phytosanitary situation within their territories. It must be recognized, however, that although science has become increasingly important in the process of decision-making, other factors such as politics and economics will continue to play a role in the process.

A common misconception is that countries that are not planning to export are not impacted by the SPS Agreement. Both importing and exporting countries need to be able to justify the application of SPS measures to their trading partners and to their own consumers, producers, and industry groups.

Meeting the requirements of the SPS Agreement entails strengthening sanitary and phytosanitary services in several areas of competence. However, economic crises and the resulting budget constraints have resulted in significant challenges to achieve full compliance. To bridge this gap, official sanitary and phytosanitary services in many countries have resorted to the accreditation of private professionals to carry out official actions, to privatization of services under the regulation and supervision of the state and have also implemented schemes of mixed financial participation with specific objectives such as disease eradication campaigns (Zepeda, 1998).

Sound science is the cornerstone for successful implementation of the SPS Agreement.

Introduction

Root and tuber crops are plants yielding starchy roots, tubers, rhizomes, corms, and stems. They are used mainly for human food (as such or in processed form), animal feed, and for manufacturing starch, alcohol, and fermented beverages including beer. Many of the developing world's poorest producers and the most undernourished households depend on root and tuber crops as an important source of food and nutrition (Scott *et al.*, 2000). Root and tuber crops produce large quantities of energy per day, in comparison with cereals. They have been playing more and more important roles in global food and energy security. The major root and tuber crops – potato, sweet potato, cassava, and yam – occupy approximately 53.93 million hectares worldwide and produce 736.747 million tonnes annually (FAO, 2008). Individually, potato, sweet potato, cassava, and yam rank among the most important food crops worldwide in terms of annual volume of production. Potato, sweet potato, and cassava rank among the top ten food crops produced in developing countries. This article describes origin and distribution, botany and physiology, breeding and cultivation, diseases and insects, and uses and economic importance of the three crops: potato, sweet potato and cassava.

Potato

Origin and Distribution

The center of origin of potato is known to be the Andes of southern Peru and northern Bolivia. The first potatoes were cultivated approximately 8000 years ago in this region, where the potato became intimately connected with Andean culture and religion and was reflected in myths and legends describing the bounties of the Pachamama or Mother Earth. The historical record of the first European to see potatoes was in 1537, when a band of Spaniards led by Jiménez de Quesada penetrated into the highlands of what is now Colombia. Potato in Chile received first mention by Francis Drake in 1578. Apparently there were two introductions into Europe, one into Spain in 1570 and the second into England in 1590. Potatoes in the North American colonies were received first from Bermuda in 1691. British missionaries took potatoes to India and China in the seventeenth century and they were introduced into Japan and parts of Africa at about the same time. They appeared in New Zealand in 1769 and were grown by the Maoris by 1840. Thus, the potato became one of the important crops in more than 300 years (Hawkes, 1994). Now, there are more than 150 countries growing potatoes. The most important cultivated potato belongs to the species, *Solanum tuberosum* L., 2n = 4x = 48. In addition to *S. tuberosum*, there are seven other cultivated species and 228 wild species. They possess the same base number ($x = 12$) of chromosome as the cultivated potatoes and range from diploid ($2n = 2x = 24$) to hexaploid ($2n = 6x = 72$) (Hawkes, 1994).

Botany and Physiology

Cultivated potato is a vegetatively propagated crop. A potato tuber, actually a modified stem, is both a storage organ and a reproductive organ. The face of each tuber has 'eyes,' which are undeveloped leaf buds. Each eye has three buds, one being primary and the others axillary. When the tubers for breaking dormancy eyes begin to grow while exposed to light, they generally form short stem with leaves. As potato stems elongate, leaves form in a spiral pattern; the first leaves forming at the bottom of the plant and the younger leaves developing from the top as the stem continues to grow upward. Each point where a leaf attaches to the stem is called a 'node,' and each attachment point to the stem represents a single compound leaf, which consists of a terminal leaflet and a row of opposite leaflets all attached to a petiole.

Early- or short-season potato cultivars are often limited to vine growth. These plants will generally form 10–13 leaves and then produce a flower. Once the leaves and flowers have matured, further vine growth stops. Long-season potato cultivars are often 'indeterminate,' meaning that vine growth and flower production continue throughout the season. As with short-season cultivars, the first inflorescence will occur at the 10th–13th node. However, growth does not cease at this point, and one of the side or axillary buds just below the flower will begin elongating into a new stem, which will produce another inflorescence. With a sufficiently long season and good nutrition, this process can repeat.

The flowers are actinomorphic and calyx. The five stamens alternate with the petals and are borne on the corolla tube. The anthers enclose the pistil. At maturity, the stamens have short, stout filaments and long anthers. Pollen is shed through pores at the tips of the anthers. There are usually two carpels, the primordia of which are formed simultaneously. These fuse to form a syncarpous, bilocular, superior ovary with a long style and a bilobed stigma. Under proper condition, flower can pollinate and develop into a mature fruit and seed. Each seed inside of a potato fruit is genetically different, and each seed is potentially a new potato variety. Potato breeders use these fruits to produce new varieties.

Once the potato vines are well established, plants will produce stolons underground, which are modified stem that grow horizontally. With appropriate conditions, the tips of stolons will soon hook and begin to swell, resulting in the initiation of new tubers.

Breeding

Cultivated potato from *S. tuberosum* is a tetraploid, which displays tetrasomic inheritance. The crossbreeding is main breeding method of potato. Compared with other crops, because the parents are not homozygous, potato F_1 is a segregating population. Although regional breeding procedures have certain differences, the basic process is the same (Table 1).

At present, most widely cultivated varieties are created by crossbreeding or natural pollination seeds. The main breeding targets may differ between countries or regions. Generally speaking, the concerns mostly include tuber yield, maturity, resistance to biotic and abiotic stresses, and characteristics of tubers like size, shape, nutrient components, etc. There are several famous potato varieties in the world worth mentioning. Much elder one is 'Bintje,' bred by K. L. de Vrie, Netherlands in 1905 from a cross between 'Munstersen' and 'Fransen.' It produces a moderate to high yield and has moderate drought resistance. Tubers are oval to long oval with smooth, pale yellow skins. It is the variety which cooks slightly moist and firm, with light yellow flesh and good shape. Now the variety is widely used for genetic engineering research as it has the good culture response *in vitro*. 'Russet Burbank,' another well-known potato variety, was identified and selected by Lou Sweet of Colorado in 1914. The tuber is long, slightly flattened with medium russet skin. Russet Burbank has good storage, processing, and culinary qualities. Currently, widely used chip variety is 'Atlantic,' which was released in 1978 by the USDA-ARS-Beltsville. Its tubers are round to oval and buff colored. It is suitable for processing into potato chips directly from the field and from short-term storage. A famous French fry variety is 'Shepody,' which was released in 1980 by Agriculture Canada in New Brunswick. Tubers are long and white skinned with light netting. The utilization is direct-delivery processing into frozen-fried products. Up to now, there are more than thousands of potato varieties in the world, of which more than 300 varieties have been developed in China in the past 50 years.

Recognition of the primary sources of genes for disease and pest resistances lacking in cultivars of *S. tuberosum* has led to numerous collecting expeditions during the early twentieth century. Several potato germplasm collections have been established worldwide: the Vavilov collection in Russia, the Dutch–German genebank in Braunsweig, Germany, the Commonwealth Potato Collection (CPC) in the UK, the US potato genebank in Sturgeon Bay, the wild species collection at Balcare in Argentina, and mainly *S. tuberosum* varieties collection in Chile. Probably the largest collection has been established at the International Potato Center (CIP) in Peru.

In the origin centers of diversity from South America, 228 wild tuber-bearing *Solanum* species have been recognized, according to the latest taxonomic interpretation and partitioned in 21 taxonomic series. There are two barriers in interspecific hybridization between *Solanum* species. One is prezygotic barriers and the other is postzygotic barriers. Prezygotic barriers are expressed between pollination and fertilization as nongermination of pollen on stigma; germination, but no penetration into stigma; or penetration, but inhibition of pollen tube growth to ovary or ovule. Postzygotic barriers are expressed during and after fertilization in ovules, or more specifically, in embryo sacs and also during growth and flowing of F_1 plants or even later in generations. Embryo development may be arrested in its early stages due to the acting of deleterious genes, due to degeneration of the suspensor of the embryo cutting off the nutritive supply, and most frequently due to endosperm degeneration (Hermsen, 1994). Endosperm failure is associated with endosperm balance number (EBN). To explain the crossing behavior of different species, each species is assigned a hypothetical value in the endosperm. The hypothetical value is named EBN. An interspecific hybrid embryo is obtained when both parent species have the same EBN. EBN can be manipulated by 2n gametes or mitotic chromosome doubling and by haploidization (Carputo *et al.*, 1997). The role of 2n gametes in overcoming critical stages in introgression breeding schemes has been well documented, in which the use of bridging species has also been exploited to bring introgression from distantly related species to potato cultivars (Carputo *et al.*, 2000); also, the favorable alleles of 2x parent can be transferred to the 4x cultivars via 2n gamets (Ortiz *et al.*, 1997).

Somatic hybridization may be a rapid and efficient way to get the interspecific hybrid. In this approach, the success of somatic hybridization of some wild species with *S. tuberosum* demonstrates its potential because most of the somatic hybrids introgressed the valuable trait, like resistance, from distant

Table 1 General breeding procedure

Season 1	Sexual hybridization. Greenhouse crosses or field crosses in proper condition. The true seeds are harvested from each cross
Season 2	Potato family populations are developed by planting the seeds to grow minitubers
Season 3	The potato family minitubers are planted 1–4 hill in the field. Selections are made on phenotypic characteristics – appearance field, disease resistance, and maturity
Season 4	Selected tuber clones are planted in the field as 5–10 hill. Evaluation is conducted in the field for integrative plant performance and the selections are harvested
Season 5	Selected clones are planted 10–20 hill in a 2-replecation trial and go through another year of phenotypic evaluations, selections, disease testing, and quality testing
Season 6	The field evaluation for the selected clones are carried out with three replicated agronomic trials. Selections are recognized as advanced breeding lines. These lines are transferred to tissue culture laboratory where virus- and disease-free plantlets are grown on nutritional media in test tubes
Season 7–8	During these seasons, regional test organized by authorities is conducted. Adaptation, tuber quality, and disease and insect resistance are further evaluated
Season 9–10	On-farm trials are carried out. Large-scale agronomic and storage testing are conducted. Variety Release and Plant Variety Protection is considered. Certified potato seed tuber production is initiated. Contracts with seed growers are prepared

species to cultivated variety (Zimnoch-Guzowska *et al.*, 2003) and some somatic hybrids can be sexually backcrossed to potato cultivars (Helgeson and Williams, 1991; Guo, 2011).

Genetic transformation has gained its fast development in potato. It is potentially the shortest procedure for introgressing alien genes into a crop species, and hybridization barriers are not relevant. Transformed cells must have the ability to regenerate into plants. Fortunately, the potato in general has a good regeneration and transformation ability, but the genetic differences are the limited factors for making progress with certain genotypes. Another drawback may be somaclonal variation among the regenerated transgenic plants.

With the development of molecular biology, many important genes have been identified from potato. Elucidation of gene functions has opened brand avenues for understanding the genetic network and manipulating the performance of a trait. Some *R* genes resistant to potato late blight have initiated pyramid breeding by using more and more *R* genes in a variety against this disease. The global transcriptomics have identified at least 428 genes contributed to the quantitative resistance of potato to late blight (Wang *et al.*, 2005; Li *et al.*, 2009), some of them have been cloned and functionally tested to play critical roles in the resistant pathways.

The genes related to tuber quality may be represented by *StvacInv1* and *StInvInh2*, which encode potato vacuolar invertase and the invertase inhibitor. These two genes have recently been well documented to control the reducing sugar content of cold-stored potato tubers through their interaction (Liu *et al.*, 2013). The reducing sugar content is a key factor influencing quality of frying products, because of which most of the potato varieties are not suitable for frying processing.

Other genes which are lacking in potato cultivars could be identified in wild species and relative cultivated specie, such as species showing pest resistance, frost and draught resistance or tolerance, specific nutrient components, etc. Development in high-throughput sequencing in combination with the platforms of proteomics, metabolomics, as well as computational tools will accelerate the innovation to deepen the understanding in how a trait have been controlled and how to control a trait more efficiently.

Cultivation

Potatoes are grown in a wide variety of regions more than other crops, except maize, that is, from tropic to temperate zone and from sea level to 4000 m high hills. Although potatoes can grow under various environmental conditions, an appropriate cultivation is essential for a good harvest.

Like other vegetatively propagated plants, degeneration caused by viruses is one of the main factors impacting on tuber yield. Use of certified seed tubers, which are produced initially by *in vitro* virus elimination and subsequent propagation in protected region and selected fields for minimizing disease and insect infection, can be the first choice to ensure a high yield. A desirable size of seed tubers is approximately 50 g. The seed tuber bears a number of sprouts; a sprouting level represents the physiological age of the tuber. Relatively younger seed tubers would have a stronger capacity of production.

Each seed tuber can develop a various number of stems, a variety-dependent trait but largely associated with mother tuber size. Because each stem has its own root system and forms tubers independently, number of stems per unit area is propitious to term the plant density of a potato crop. Many experiments have proved that number of tubers and tuber size are strongly affected by number of stems. A negative exponential model developed by Xie (1989) is predicable to estimate tubers of each size category. The higher the plant density is, the more the tubers and smaller the tuber size will be. A desirable plant density is determined by the variety used and demand for the products. For example, large tubers are profitable for a ware crop and a relative small size is better for seeds; therefore, a lower plant density can more easily be applied to the former than to the latter.

Field management is important for any crop. Mineral nutrition required by the plants is obtained from the soil and fertilizers applied. Potatoes need optimal level of essential nutrients throughout the growing season to ensure normal plant growth and tuber development. Potato plants with tuber yields that range from 50 to 60 ton ha^{-1} will take up approximately 220–270 kg N, 28–40 kg P, 310–360 kg K, 20–27 kg S, 55 kg Ca, 45 kg Mg, 2 kg Fe, 0.2 kg B, 0.1 kg Zn, 1 kg Mn, and 0.1 kg Cu. Potatoes usually take up approximately 40–50% of their seasonal nitrogen and potassium requirements and approximately 30–40% of their phosphorus and sulfur requirements by the time tuber bulking begins.

High tuber yields are dependent on an adequate supply of soil water, and water supply is a major cause of year-to-year variation in yield. Potato yield can be reduced by both over- and underirrigation. Generally, approximately 10% deviation from optimum water supply for the growing season may begin to decrease yield. Available soil moisture in the root zoon (0–45 cm) should be maintained at 65% to avoid yield and quality losses. Normally, it is better to keep the available soil moisture between 70% and 85% during the active growth period for optimum results (**Figure 1**).

Diseases and Insects

Potatoes are easily attacked by many kinds of pathogens which cause serious yield loss. The most devastating disease of potato is late blight, which leads to losses of billions of dollars annually to modern agriculture and also impacts on subsistence farming in developing countries (Kamoun and Smart, 2005). Late blight is caused by the oomycete pathogen *Phytophthora infestans* (Mont.) de Bary, which induced the Irish famines in the mid-nineteenth century. *P. infestans* is an adapted pathogen that can affect the whole plant of potato. Water-soaked lesions appear on foliage. The disease is favored by temperatures between 10 and 25 °C, accompanied by heavy dew or rain. Tubers infected by spores washed by rain from the leaves and stems into the soil have brownish surface discoloration and finally rotted. Sources of inoculum are mainly neighboring fields of potato or tomato. Soil survival occurs wherever the oospores exist as a result of the presence of the A1 and A2 mating types, which can lead to early infection. There are cultivars with various levels of resistance. However, the disease is mainly controlled by spraying protective and/or systemic fungicides.

(a) (b)

Figure 1 Potato plants in a field (a) and storage tubers harvested (b).

Many fungal diseases are well described. The widely occurred ones include powdery scab of tubers caused by *Spongospora subterranea*; ward – the tumors developed on stems, stolons, and tubers – caused by *Synchytrium endobioticum*; pink rot of tubers caused by *Phytophthora erythroseptica*; powdery mildew of leaves caused by *Erysiphe cichoracearum*; early blight that can infect both leaves and tubers, caused by *Alternaria solani*; and stem rot (*Sclerotium rolfsii*) and black rot (*Rosellinia* sp.); both result in rot of stem base just below the soil line. Host resistance and fungicides are available for control of most fungal diseases.

Some important diseases are caused by bacteria. The well-known one is bacterial wilt, which is the most serious bacterial disease of potato in warm regions of the world. The pathogen *Ralstonia solanacearum* infects phloem of stem and results in wilt of part of leaves, branches, or whole plant. Latent tuber infection occurs when infected seed is planted in cool locations or in tubers infected late in the growing season. Wilt develops rapidly at high temperatures. Neither the high-level resistances in cultivated varieties have been identified, nor are there any efficient chemical available for bacterial wilt control. Crop rotation is most effective with race 3 (also known as potato strain) of the pathogen but difficult with race 1, which also infects many other crops and weeds.

Bacterial diseases widely distributed also include blackleg (*Erwinia* spp.), ring rot (*Clavibacter michiganensis* ssp. *sepedonics*), and common scab (*Streptomyces scabies*). Using healthy seed is recommended. Overirrigation should be avoided for control of blackleg and soil pH levels should be maintained at 5–5.2. Acid-forming fertilizers of sulfur for control of common scab are preferable.

More than 20 viruses and viroids can infect potatoes, resulting in serious yield loss known as 'degeneration.' The most important potato viruses are considered to be eliminated in many seed potato certification systems, including Potato Virus X (PVX), Potato Virus Y (PVY), Potato Leaf Roll Virus (PLRV), Potato Virus A (PVA), Potato Virus S (PVS), Potato Virus M (PVM), as well as Potato Spindle Tuber Viroid (PSTV). Potato plants can be infected by a single virus or by multiviruses, the latter usually cause much more severe plant symptoms than caused by the former. Resistance to individual viruses can be found out in modern varieties, but a pyramid breeding is not applicable to build up the multiresistance to all these important pathogens; degeneration would occur if a variety is susceptible to any of the viruses. Therefore, the most effective way of controlling virus diseases is adaptation of the seed potato certification system, by which healthy seeds can be supplied.

Nematodes are a serious cause of potato diseases in some of the main potato-growing areas. Cyst nematodes (*Globodera pallida* and *G. rostchiensis*) are native to Andes and have now spread to some temperate zones and high-altitude tropics. Root-knot nematodes (*Meloidogyne* spp.) occur normally in warm regions, particularly in sandy soils. These two nematodes also increase incidence of infection by bacterial and *Verticillium* wilt. Other nematodes include false root-knot nematodes (*Nacobbus aberrans*) and lesion nematodes (*Pratylenchus* spp.) that occur in cold Andean areas and in temperate climates. Use of healthy seeds and long rotation can reduce the damage caused by nematodes.

In addition to the green pitch aphid (*Myzus persicae*) – the most important potato aphid that can damage plants directly by feeding and indirectly by transmitting viruses to the plants – the potato tuber moths (*Phthorimaea operculella*, *Symmetrischema plaesiosema*, *Tecia solanivora*, and *Srobipalpula absoluta*) and the Colorado potato beetle (*Leptinotarsa decemlineata*) have attracted great attention because of their increasing impact on yield and difficulties for control.

Potato tuber moths attack potatoes in both fields and stores. They are widely distributed in warm, dry areas. *P. operculella* is the most damaging type and is generally of greatest importance in warmer climates; the larva can bore through the plant terminals and stems, mine the leaves, and bore through the tubers in the field. Severe damage can occur in stores in a short time. *S. absoluta* damages only leaves and sprouts, whereas both *S. plaesiosema*and *T. solanivora* principally attack tubers in stores. The pest incidence can be reduced through cultural practices such as not planting potato in the warmest and driest seasons, proper irrigation to prevent soil cracking that allows moth to reach the tubers, and occasionally using a selective insecticide. Biological insecticide treatments such as *Bacillus thuringiensis* or *Baculovirus* can be used with tubers in stores.

The Colorado potato beetle is an insect dangerous to potato in North America and some other areas of the world. Potato yields are reduced and plants are sometimes killed by adult and larval leaf feeding. More serious yield loss can be caused by leaf feeding when it occurs within 2 weeks of flowering. The high reproductive potential, and the fact that this insect has become resistant to almost all insecticides used against it, make Colorado potato beetle difficult to control. Crop rotation can help to delay or reduce beetle pressure. Control of volunteers and weeds can limit the early food source of overwintering beetle adults. Chemical control is a main way but should be rotated with each application to avoid development of resistance to any one compound.

Uses and Economic Importance

In 2008, the United Nations declared the International Year of Potato with the slogan 'Hidden Treasure.' This global activity has attracted attention on the role of potato providing food security and eradicating poverty in support of achievement of the internationally agreed development goals including the Millenium Development Goals (Lutaladio and Castaldi, 2009). There are more than 1 billion undernourished people in the world and majority of them live in developing countries. The poorest and most undernourished farm households depend on potatoes as a primary or secondary source of food and nutrition. The potato produces more nutritious food more quickly on less land and in harsher climate than any other major crops. It is estimated that the world potato demand is going to double by 2020 of that in 1993. Besides for human consumption, potatoes can also be used for industrial purposes such as starch production. Potato starch can be processed in textile, papermaking, glue, coating, sizing, flocculating agents, and building materials. More uses can be anticipated for the future, such as in biopharmaceuticals for encapsulation and controlled release of functional ingredients.

According to the statistics of FAO (http:faosta.fao.org), in 2011, the potato area harvested in the world was 19.25 million hectares with output of 374.38 metric tonnes. The gross production value of potato was accounted for 2.64% of that of agriculture in total. The world potato sector is undergoing tremendous changes. Until the early 1990s, most potatoes were grown and consumed in Europe, North America, and countries of the former Soviet Union. Since then, there has been a dramatic increase in potato production and demand in Asia, Africa, and Latin America, where output rose from less than 30 million tonnes in the early 1960s to more than 165 million tonnes in 2007. FAO data show that in 2005, for the first time, the developing world's potato production exceeded that of the developed world (http://www.potato2008.org/en/world/index.html). China is now the biggest potato producer, and almost a third of all potatoes is harvested in China and India.

Accelerated and sustainable development of the potato sector is essential both to guarantee the food security of the world's growing population and as a source of added value to drive economic development in countries dependent on agriculture. Potato is already helping in development and food security in Africa, Asia, and Latin America, where potatoes have become an important staple food and cash crop. But further progress requires both increases in the productivity, profitability, and sustainability of potato-based farming systems and a stronger commitment by the international community to agricultural and rural development.

Sweet Potato

Origin and Distribution

Sweet potato, *Ipomoea batatas* (L.) Lam., was originally domesticated at least 5000 years ago in tropical America (Yen, 1982). The exact center of origin and domestication of sweet potato has not been well defined, nor has the wild ancestor of this species been found (Rossel *et al.*, 2001). Based on the numerical analysis of key morphological characters of sweet potato and the wild *Ipomoea* species, Austin (1988) postulated that sweet potato originated in the region between the Yucatán Peninsula of Mexico and the Orinoco River in Venezuela, within which the four major American taxa of the *batatas* group are distributed. Recent reports using molecular markers to assess diversity have found the highest diversity in Central America, supporting the hypothesis that Central America is the primary center of diversity and most likely the center of origin of sweet potato (Huang and Sun, 2000; Zhang *et al.*, 2000).

Sweet potato was one of the first plants introduced from the Americas into Europe by Columbus in 1492. From Europe, this crop was taken by the Portuguese explorers of the sixteenth century to Africa, India, Southeast Asia, and the East Indies. This is the so-called '*batata* line' of dispersal. The *camote* line (from the Nahuatl word *camotli*) represented the direct transfer of Mexican sweet potatoes by Spanish trading galleons between Mexico and the Philippines in the sixteenth century (Rossel *et al.*, 2001). In the Asia and Pacific region, there have been complex interchanges of sweet potato after early introductions. The introduction of sweet potato to the Pacific islands before the era of European exploration was considered to be the third line of prehistoric transmission (Yen, 1982). Fossil carbonized storage roots of sweet potato found in northern New Zealand have been dated back to approximately 1000 years (Yen, 1991), probably by Peruvian or Polynesian voyagers (Yen, 1982). The linguistic links between the Quechua and Polynesian names for sweet potato, and their variations, support the Peruvian origin and human transfer of the Polynesian sweet potato (Rossel *et al.*, 2001). The successful drift voyages of the Kon-Tiki expedition in 1947 (Heyerdahl, 1950) further put this sweet potato issue within the context of the wider problem of the origin of the Polynesian people. Using complementary sets of markers (chloroplast and nuclear microsatellites) and both modern and herbarium samples, Roullier *et al.* (2013) provide the support for prehistoric transfers of sweet potato from South America (Peru–Ecuador region) into Polynesia. Today, the 'Kumara' area includes many sweet potato-producing countries in Oceania, including New Zealand, Tonga, Samoa, and the Cook Islands (Yen, 1974), where sweet potato is a widely used staple food.

Sweet potato is an ancient crop of Peru (Yen, 1974; Austin, 1987). Examples unearthed at numerous archeological sites representing both Inca and preInca cultures suggest that sweet

potato was one of the most important crops in this region (Urgent and Peterson, 1988). However, whether Peru was a major source of sweet potato to Oceania is still unsettled. The studies based on molecular markers showed that Peruvian sweet potatoes were not closely related to those from Papua New Guinea (Zhang *et al.*, 1998) and were also different from those of Mesoamerica (Zhang *et al.*, 2000). Understanding the level of genetic diversity and geographic differentiation is critically important to germplasm conservation. Conservation strategies and methods depend largely on this kind of information from within a given gene pool (Rossel *et al.*, 2001). It was suggested that the sweet potato from Oceania probably came from Central America through nonhuman dispersal (Rossel *et al.*, 2001). The crop was apparently introduced to China in the late sixteenth century by ship from Luzon in the Philippines to Fujian of China (O'Brien, 1972). Other data give information that sweet potato was introduced to China from Vietnam, India, and Burma. Extension of sweet potato inside China was apparently from south to east along the coast and from south to north through the Yangtze River and the Yellow River valleys.

In 2000, CIP published *A Global Geo-Referenced Database of Sweetpotato Distribution*, by Huaccho and Hijmans, based on data from many country-level sources and the Food and Agriculture Organization of the United Nations (FAO). Hijmans, through updating the Database, described a new global geo-referenced database of the distribution of sweet potato and used it to provide a preliminary description of the current distribution of the crop. The results are as follows: sweet potato is grown in areas where it can be grown year round as well as in areas where it can be grown only in the summer (warm) season and approximately half the global sweet potato area occur where it is an obligatory seasonal crop because of low temperatures during part of the year. Most sweet potatoes are grown in the temperate zone between 20°N and 40°N. This peak includes nearly all the areas in China, India, and North America. The sweet potato area at these latitudes is virtually all in lowlands. The second peak in sweet potato distribution by latitude is between 10°S and 15°N. This peak includes most of the sweet potato areas in Africa and some areas in Asia and northeastern Brazil. A large part of the sweet potato areas at these latitudes occur at mid-elevation.

Botany and Physiology

Sweet potato is a member of the family Convolvulaceae, Genus *Ipomoea*, section *Batatas*. The number of chromosomes in the sweet potato plant is 2n = 6x = 90. This indicates that it is a hexaploid plant with a basic chromosome number x = 15. Among the wild species, *I. tabascana* and *I. tiliacea* are tetraploids with 2n = 4x = 60. The other species are diploids with 2n = 2x = 30. Polyploid species are *I. cordatotriloba* with 2x and 4x and *I. trifida* with 2x, 3x, 4x, and 6x (Huaman, 1992). Morphological analysis of the related species indicates that *I. trifida* is the closest wild relative to sweet potato but *I. tabascana* is also morphologically very close (Austin, 1977, 1987). Austin (1987) suggests that natural hybridization between *I. trifida* and *I. triloba* resulted in generation of the wild ancestors of the present *I. batatas* (L.) Lam., Jarret *et al.* (1992) supported a hypothesis that *I. trifida* (H.B.K.) G. Don and wild Mexican tetraploids are putative ancestors of the cultivated sweet potato. Species in section *Batatas* have been shown to contain unreduced gametes (Bohac and Jones, 1994), but the derivation of the hexaploid sweet potato remains unknown. Shiotani (1988) considered it an autopolyploid derivative of *I. trifida*, whereas others favor an allopolyploid origin involving *I. trifida* and an unidentified tetraploid parent. Tetrasomic segregation patterns in microsatellite primers are consistent with an allopolyploid (Buteler *et al.*, 1999). Zhang *et al.* (2001) also found tetrasomic patterns of inheritance in sweet potato. The most compelling evidence of an allopolyploid origin is cytological data reported by Magoon *et al.* (1970). Meiotic patterns showed various pairing configurations among the chromosomes, for example, duplicate, triplicate, and quadrivalents. Their data suggest that *I. batatas* consists of two related and a third more distant genome (Firon *et al.*, 2009).

The cultivated species, *I. batatas* (L.) Lam., includes plants that are very variable in their morphology. Sweet potato is a herbaceous and perennial plant. However, it is grown as an annual plant by vegetative propagation using either storage roots or stem cuttings. Its growth habit is predominantly prostrate with a vine system that expands rapidly horizontally on the ground. The types of growth habit of sweet potato are erect, semierect, spreading, and very spreading.

The sweet potato root system consists of fibrous roots, which absorb nutrients and water and anchor the plant, and storage roots that are lateral roots, which store photosynthetic products. A sweet potato stem is cylindrical and its length depends on the growth habit of the cultivar and on the availability of water in the soil. The stem color varies from green to totally pigmented with anthocyanins (red-purple color). The hairiness in the apical shoots, and also in the stems of some cultivars, varies from glabrous (without hairs) to very pubescent. The leaves are simple and are spirally and alternately arranged on the stem in a pattern known as 2/5 phyllotaxis. The edge of the leave lamina can be entire, toothed, or lobed. The shape of the general outline of sweet potato leaves can be round, reniform (kidneyshaped), cordate (heart shaped), triangular, hastate (trilobular and spear shaped with the two divergent basal lobes), lobed, and almost divided. The leaf color can be green yellowish, green, or can have purple pigmentation in part of or the entire leaf blade. The leaf size and the degree of hairiness vary according to the cultivar and environmental conditions (Huaman, 1992).

Sweet potato cultivars differ in their ability of flowering. Under normal conditions in the field, some cultivars do not flower, some produce very few flowers, and others flower profusely. The inflorescence is generally a cyme in which the peduncle is divided in two axillary peduncles; each one is further divided in two after the flower is produced (biparous cyme). Some cultivars produce white flowers. The flower is bisexual. The androecium consists of five stamens, and the anthers are whitish, yellow, or pink. The gynoecium consists of a pistil with a superior ovary, two carpels, and two locules that contain one or two ovules. The stigma is receptive early in the morning and the pollination is mainly by bees. The fruit is a capsule, more or less spherical with a terminal tip, and can be pubescent or glabrous. The capsule turns brown when mature. Each capsule contains from one to four seeds that are slightly

flattened on one side and convex on the other. Seed shape can be irregular, slightly angular, or rounded; the color ranges from brown to black; and the size is approximately 3 mm. The embryo and endosperm are protected by a thick, very hard, and impermeable testa. Seed germination is difficult and requires scarification by mechanical abrasion or chemical treatment. Sweet potato seeds do not have a dormancy period but maintain their viability for many years (Huaman, 1992).

The storage roots are the commercial part of the sweet potato plant, and sometimes are mistakenly named 'tubers.' Most cultivars develop storage roots at the nodes of the mother stem cuttings that are underground. However, the very spreading cultivars produce storage roots at some of the nodes that come into contact with the soil. The parts of the storage roots are the proximal end that joins to the stem, through a root stalk, and where many adventitious buds are found from which the sprouts are originated; a central part which is more expanded; and the distal end that is opposite to the root stalk. The adventitious buds that are located in the central and distal part usually sprout later than those located in the proximal end.

Breeding

Crossbreeding is the main breeding method for sweet potato. Two major difficulties have been encountered in the development of sweet potato's scientific-breeding methods. First, sweet potato is polyploidy. Second, it is almost always self-incompatible and male sterile. However, since the 1950s, breeding programs have been implemented, mostly in temperate climates, in the US, China, and Japan.

Rossell *et al.* (2007) reported that more than 6000 accessions of landraces, breeding lines, and advanced cultivars of sweet potato were held by CIP in its genebank. The choice of varieties to grow appears to depend largely on how the produce – the root – are utilized, whether as food either directly or in processed forms, as feed component, or as sources of industrial starch. For food varieties, preferences also seem to vary among and even within countries. The dominant varieties in some of the major sweet potato-growing countries are presented below (Carpena, 2009).

In China, 'Xushu 18' (purple skin and white-yellow flesh) was bred by Xuzhou Agricultural Research Institute, Jiangsu in 1972 and is today the leading variety with an annual area of 1.5 Mha. 'Nanshu 88' (pale red skin and pale yellow flesh) was released in 1988 by Nanchong Agricultural Research Institute, Sichuan and is mainly used for food as fresh roots and feed processing (Zhang *et al.*, 2009).

In the US, the leading variety, 'Beauregard' (copper-rose skin and yellow flesh), is a polycross selection released by the Louisiana State University and occupies nowadays approximately 65% of the area planted annually (Smith *et al.*, 2009). Another important variety in the US is 'Covington,' released by North Carolina Agricultural Research Station in 2005, which is estimated to occupy 30% of the sweet potato production area (Carpena, 2009).

In Japan, the leading table variety, 'Beniazuma' (deep red skin and yellow flesh), was released by the National Institute of Crop Science in 1981 and new cultivars with high anthocyanin content and high yields are being developed. 'Ayamurasaki,' for example, is now recommended as a superior source for the production of foods with health benefits (antioxidants) and some foods and beverages already use the anthocyanin pigments (Suda *et al.*, 2003).

In Uganda, 'Tanzania,' a selection from Ugandan landrace germplasm is the most widely grown sweet potato variety and was officially released in 1995, along with three other landrace selections, namely, 'New Kawogo,' 'Bwanjule,' and 'Wagabolige' and a selection from the progenies of a polycross involving 18 popular farmers' cultivars in Uganda, namely, 'Sowola' (Mwanga *et al.*, 2001).

In Papua New Guinea (PNG), sweet potato is the no. 1 food crop, accounting for more than 60% of the total production for 18 staple food crops in 2000, based on the data presented by Bourke (2006). In 2004, the National Agricultural Research Institute released varieties resistant to scab disease (*E. batatas*) with high dry matter: 'K9,' 'B11,' 'Nuguria 5,' and 'SI 278'.

Utilization of the wild relatives of sweet potato in sweet potato improvement has resulted in the release of several varieties such as 'Minamiyutaka' (Japan) and 'Jishu 98' (China). Storage root-bearing somatic hybrids between sweet potato and its wild relatives have been developed (Yang *et al.*, 2009). Genetic engineering offers a great potential for improving disease, pest, or stress resistance as well as nutritional quality of sweet potato. Several agronomically important genes; carbohydrate metabolism-associated SRF1 and IbSnRK1; carotenoids biosynthesis-associated IbLCY-ε and IbLCYe; stress tolerance-associated SWPA2, IbNFU1, and IbP5CR; and disease resistance-associated IbMIPS have been cloned from sweet potato (Liu *et al.*, 2011; Wang *et al.*, 2013; Kim *et al.*, 2013). Transgenic sweet potato plants have been obtained, which exhibit enhanced salt tolerance, disease resistance, or herbicide resistance (Liu *et al.*, 2011; Fan *et al.*, 2012). Molecular markers linked to nematode resistance gene and QTLs for dry-matter , starch, and β-carotene content have been identified (Cervantes-Flores *et al.*, 2011; Liu *et al.*, 2011). These works represent an important step forward in sweet potato improvement through molecular breeding.

Cultivation

Sweet potato is cultivated throughout the tropics and warm temperate regions of the world. Storage root yields respond to native soil fertility. Surface soil is usually scrapped into mound, heaps, or ridges into which several crops are planted. Sweet potato cannot tolerate excessive moisture in soil or drought without irrigation. Some varieties tolerate drought or low soil moisture; however, it is suggested not to plant vines into dry soils. Some varieties tolerate moist soils near waterways and wetlands. Seedbeds (20–30 cm of loose soils) facilitate storage root thickening through less resistance to penetration. Well-drained sandy loamy soils are best, whereas heavy clayey soils produce rough bad-shaped storage roots.

Unlike most vegetables and fruit crops, sweet potatoes are not planted directly as seeds in fields and gardens. They are transplanted as cuttings, which are young shoots that emerge from storage roots. Storage roots produce cuttings in a starter bed. Planting actively growing 25–30 cm apical vines with 4–6

(a) (b)

Figure 2 (a) Sweet potato plants in a field and (b) storage roots harvested.

nodes are best, with a planting density of 45 000–60 000 plants ha^{-1} (Figure 2). The higher the plant density is, the more the storage roots and the smaller the storage root size will be. A desirable plant density is determined by the variety used and demands for the products.

Field management is important for any crop. For weed control in sweet potato, it is a common practice to apply Oxadiazon or Glyphosate before planting. Mineral nutrition required by the plants are obtained from the soil and fertilizers applied. Fields before planting are fertilized with compost and NPK. It is very important for the soil to be rich in organic matter for better soil fertility and higher water retention capacity. Sweet potato requires a generous contribution of potassium to favor the thickening of storage roots. However, excessive nitrogen fertilization causes great development of the stems but smaller storage roots. Removing weeds from around the young sweet potato slips avoids competition for nutrients. Once the plants begin maturing, their sprawling vines and leaves are often sufficient to deter weedy plants. The soil around the plants should be kept moist but not saturated. Overwatering encourages the growth of soilborne fungi that harm sweet potato plants.

According to cultivation techniques, not watering sweet potato during the last month of their growth improves the harvested roots' quality as well as prevent decay. Around October or December, when the plant leaves begin to lose its dark green color and the soil begins to crack, the storage roots are harvested. Harvesting entails cutting off shoots, carefully digging out storage roots with hoe or pickax, and then remove adhering soil (Figure 2). They are classified into three classes: the bigger and larger storage roots for consumption; the smaller and lightweight roots for the next crop; and the tiny and wounded roots for livestock.

Diseases and Insects

Although sweet potato can withstand many adversities, numerous diseases and insects have been reported on this crop from different regions of the world and the species of diseases and pests are different in different regions.

Sweet potato diseases generally fall into three types: bacterial, fungal, and virus. Major bacterial and fungal diseases include sclerotial blight (*Sclerotium rolfsii* Sacc.), black rot (*Ceratocystis fimbriata* Ell. & Halst.), scurf (*Monilochaetes infuscans* Ell. & Halst. ex Harter), foot rot (*Plenodomus destruens* Harter), and stem and leaf scab (*Sphaceloma batatas* Saw). Sclerotial blight is a common soilborne fungus that infects a wide array of crops. It is a common disease of sweet potato in the USA. Black rot has been reported on sweet potato in China, Japan, Kenya, and the USA and is apparently widely distributed (Clark and Moyer, 1988; Farr *et al.*, 2007; Kihurani *et al.*, 2000). Scurf has been reported from Africa, Asia, Australia, Europe, North and South America, and New Zealand. Foot rot has been reported as a problem in Argentina, Brazil, Burundi, New Zealand, Rwanda, South Africa, Tanzania, and the USA. Stem and leaf scab has been reported in Australia, Asia, many Pacific Islands, the Caribbean (Puerto Rico), Mexico, South America (Brazil) but is absent from the USA, except Hawaii (Farr *et al.*, 2007). It is most prominent at elevations in the tropics where conditions are wet and cool to warm.

More than 20 viruses have so far been reported to infect sweet potato, among which sweet potato feathery mottle virus (SPFMV) and sweet potato chlorotic stunt virus (SPCSV, also known as SPSVV) are the most common sweet potato viruses worldwide. Most sweet potato cultivars infected by SPFMV alone show no or only mild circular spots on their leaves or light green patterns along veins. However, when infected together with the whitefly-transmitted SPCSV stunting of the plants, feathery vein clearing and yellowing of the plants are observed (Loebenstein *et al.*, 2009).

One of the major pest groups that cause considerable damage to sweet potato is that of plant parasitic nematodes. There are a number of genera and species that feed on sweet potato. The latest report indicates that 25 genera and 55 species of nematodes are associated with sweet potato (Coyne *et al.*, 2003). The incidence of certain species can be as high as 96% of the field in some area (Iwahori and Sano, 2003) and may cause considerable losses to sweet potato. The root-knot nematodes are generally considered to be the most important nematodes in the production of sweet potato around the world. Other types of nematodes that are known to cause

serious problems of sweet potato are lesion nematode and stem nematode (Overstreet, 2009).

Most recently, 270 insect and mite species are listed as pests of sweet potato around the world. Many insects reduce the quality and yield of sweet potato, either by feeding directly on the storage roots or by defoliating leaves and/or boring into vines. Aphids, whiteflies, and leafhoppers can also transmit many of the viruses known to infect sweet potato. Sweet potato storage roots are injured by a complex of Coleopterous soil insects. Soil insects that damage the root are the most harmful ones because they can cause significant economic losses even in low numbers. In contrast, many foliage-feeding insects do not cause yield reductions because sweet potato plants can often compensate for high levels of defoliation. Insect losses reach 60–100%. The sweet potato weevil, *Cylas formicarius* Fab., is the most destructive insect affecting sweet potato. Other insects such as wireworms, rootworms, and flea beetles also cause damage to sweet potato (Sorensen, 2009).

As to sweet potato disease control, the following measures can be adopted: selecting and using the disease-resistant varieties; attaching importance to the quarantine inspection of the seed and seedlings; cultivating disease-free and strong seedlings or using virus-free seedlings; using medicaments; implementing an integrated program of crop rotation; strengthening water and fertilizer management and so on. The pest shall be controlled as follows: eliminating the pupas by cleaning the crop lands after harvest; treating seedling with medicaments; spraying chemicals on the plants during the larval phase of the pests, etc. With more attention and investment to sweet potato industry and further researches on sweet potato diseases and pests, new control methods and medicaments will be applied to sweet potato production.

Uses and Economic Importance

Sweet potato is regarded as the seventh most important food crop in the world (FAO, 2009). In most developing countries, it is a smallholder crop tolerant of a wide range of edaphic and climatic conditions and grown with limited inputs. Sweet potato provides more edible energy per hectare per day than wheat, rice, or cassava and is an essential food source with very high production per capita across the relatively humid areas of Africa. From 2000 to 2011, global sweet potato cultivation declined slightly in area harvested, yield, and production on the whole, but several years indicate some rebounding based on FAO (2011) production data.

Asia is the largest sweet potato-producing region, with approximately 80% of the world's production and more than 52% of the world's area; Africa is the second largest sweet potato-producing region, with almost 17% of the world's production and more than 42% of the world's area (**Figure 3**; FAO, 2011). The vast majority of production remains in eastern Asia; China alone accounts for approximately 72% of world production, with more than 43% of the global area (FAO, 2011). In addition to China, there are considerable concentrations of sweet potato in Cuba and Haiti in the Caribbean region; in Java (Indonesia), the island of New Guinea (both in Indonesia and in Papua New Guinea), and Vietnam in Asia; and in Africa, particularly in the Lake Victoria area (Burundi, Rwanda, Uganda, and the Democratic Republic of Congo) and in Ghana, Nigeria, and Madagascar.

Use of sweet potato as food

Storage roots are most frequently used after boiling, baking, or frying. They are also processed into starch, flour, or puree to make secondary food products. Baking sweet potatoes in country ovens has been an old mode of processing storage roots in countries viz. China, India, Japan, Bangladesh, Indonesia, Kenya, Papua New Guinea, etc. Storage roots are dehydrated to enhance the shelf life of stored roots. Canning of sweet potato is widely practiced in the US. As high as 86% of the carotene content of the roots are reported to be retained in them even after canning (Elkins, 1979). Sweet potato roots are transformed into more stable edible products like fried chips, crisps, French fries, etc., which are very popular in Japan, the USA, China, the Netherlands, Peru, etc. Sweet potato is processed into noodles in many countries of the Far East. Sweet potato leaves, although a rich source of vitamins, minerals, and proteins, have been much less used as a human food. Sweet potato green tips are used as a vegetable in some parts of the world. The nutritive value of sweet potato leaves has been attributed to the high content of antioxidants, especially phenolic compounds in them (Islam *et al.*, 2002; Yoshimoto *et al.*, 2005).

Industrial utilization of sweet potato

Sweet potato starch is commercially utilized for the production of a number of commodity chemicals like citric acid, monosodium glutamate, microbial enzymes, etc. Storage roots with 20–30% starch are one of the major sources for the commercial extraction of starch. The roots are extensively used for starch extraction in China, Japan, and Korea. Sweet potato starch is similar to any other starch source for use as a raw material for the production of alcohol (Padmaja, 2009).

Roots and vines as livestock feed

Sweet potato roots and vines have been used as animal feed for many years in China and Japan. Besides, the wastes from starch and alcohol factories are also used as animal feed. Many studies are available dealing with the use of sweet potato roots as cattle, pig, poultry, and fish feed (Padmaja, 2009).

Sweet potato as a health-protectant food

Sweet potato is increasingly recognized as a health food due to several of its nutraceutical components viz. dietary fiber, vitamin A, vitamin C, phenolic acids, carotenes, protein, amino acids, mineral nutrient, xanthophylls, anthocyanins, etc. Storage roots are considered as a highly functional, low-calorie food with antidiabetic effects (Kusano and Abe, 2000).

Cassava

Origin and Distribution

Cassava (*Manihot esculenta* Crantz), also called Tapioca in Asia; Manioc in Africa; Manioca, Yucca, and Mandioca in Latin America, originated in South America. It is a perennial woody

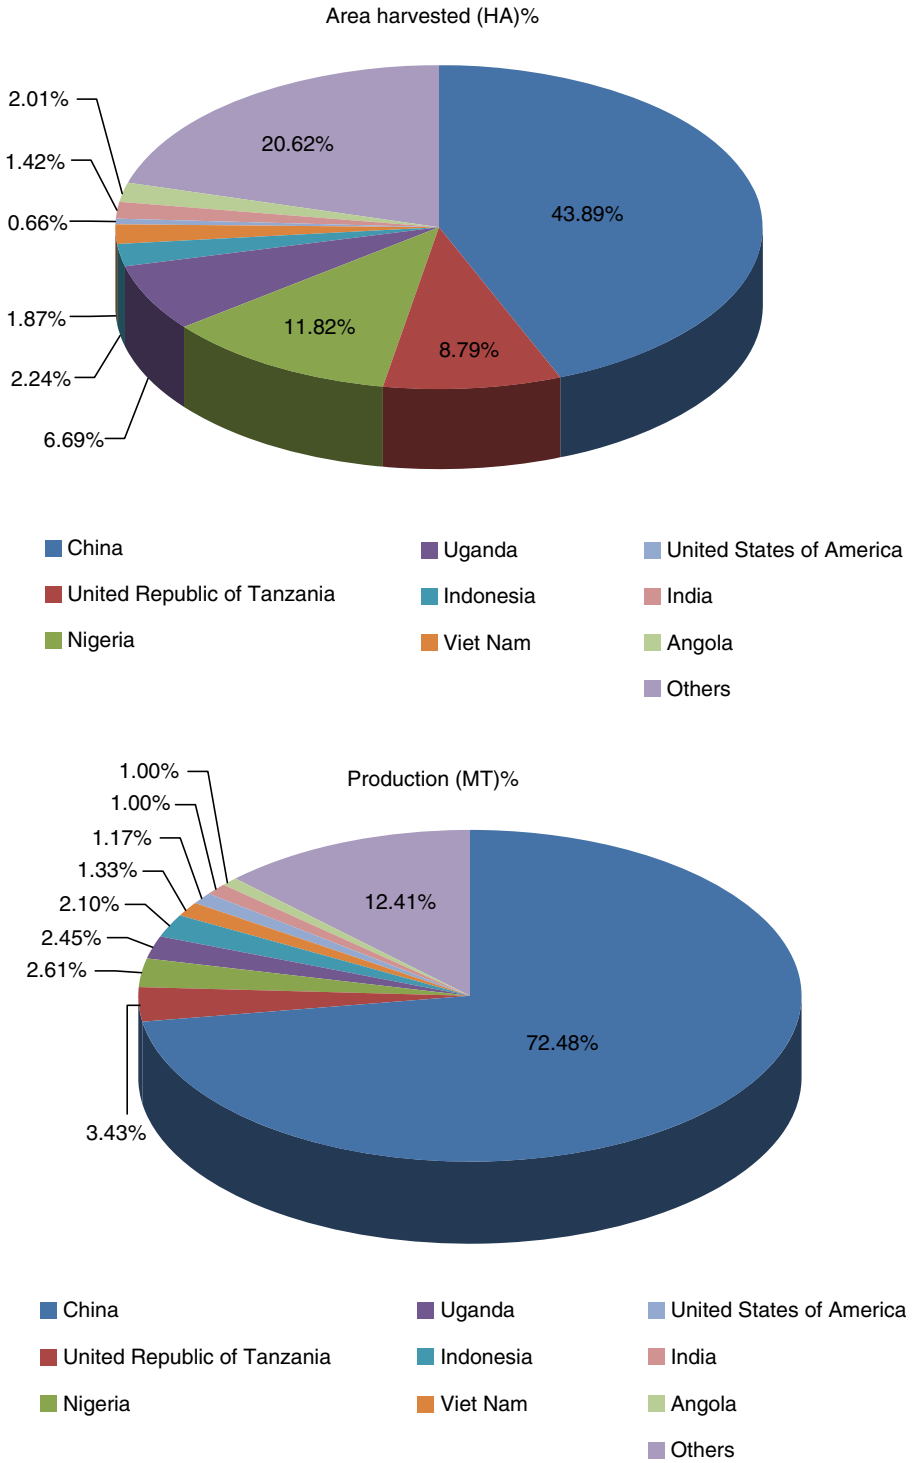

Figure 3 Sweet potato area harvested (7 953 196 ha) and production (104 259 988 metric ton (MT)) of leading countries and geographic groupings in 2011 (FAO).

shrub of the Euphorbiaceae (spurge family) and has been extensively cultivated as an annual crop in tropical and subtropical regions for its edible starchy, tuberous root (Figure 4(b)). The *Manihot* genus has approximately 100 species, and cassava is the only commercially cultivated one. Wild populations of *M. esculenta* subspecies *flabellifolia*, shown to be the progenitor of domesticated cassava (Olsen and Schaal, 1999), are centered in west-central Brazil, where it was more likely first domesticated more than 10 000 years ago. By 6600 BC, cassava pollen appears in the Gulf of Mexico lowlands, at the San Andrés archeological site. The oldest direct evidence of cassava cultivation comes from a 1400-year-old Maya site, Joya

(a) (b)

Figure 4 (a) 10-month old cassava plants in a field and (b) storage roots harvested from 10-month old cassava plants.

de Cerén, in El Salvador, but the species *M. esculenta* more likely originated in Brazil and Paraguay.

Cassava cultivation most probably began from northeast part of Brazil/Paraguay to Mexico/Guatemala more than 4000 years ago. It was introduced to west coast of Africa in the year 1588 by Portuguese traders after discovery of American continent and cultivated in Gulf of Guinea and the Congo Basin first. Around 1750, the cultivation of cassava was spread to Madagascar and east coast of Africa. And in the middle of the nineteenth century, cassava became more and more important as staple food and was widely planted in Africa between 15 degrees latitude north and south. From the very beginning of the eighteenth century, Spanish merchants used to transport cassava seedlings into India for large-scale plantation. At the end of the eighteenth century, cassava was widely spread in Asia and was planted in Indonesia, Sri Lanka, Malaysia, and other countries of tropical and subtropical Asian regions. Nowadays, as an important tropical crop, cassava's horizontal distribution is restricted between 30 degrees latitude north and south; vertical distribution is under altitude of 2000 m. The global cultivation area is approximately 19 million hectares: 55% in Africa, 27% in Asia, and 18% in Latin America (FAO, 2012).

Botany and Physiology

Owing to highly variable genetic diversity, the phenotypes of different germplasms are highly variable (Alves, 2002). However, different cassava possesses the same organs such as roots, leaves, stems, flowers, and seeds. Storage roots are the main storage organ of cassava, which accumulate plenty of starch (Figure 4(b)). The storage roots result from secondary growth of the fibrous roots, which contain three distinct tissues: bark (periderm), peel (or cortex), and parenchyma. The typical composition of the cassava storage roots is moisture (70%), starch (24%), fiber (2%), protein (1%), and other substances including minerals (Tonukari, 2004). Leaves of cassava are palmate, with uneven number of lobes, generally ranging from three to nine. The adaxial surface is covered with a shiny, waxy epidermis, and most stomata are located on the abaxial surface of the leaves. Cassava is a monecious species, which produces both male (pistillate) and female (staminate) flowers on the same plant. The fruit of cassava is a trilocular capsule with six straight, prominent longitudinal ridges or aristae. Each locule contains a single carunculated seed.

Owing to low fertility of seeds, cassava is usually propagated by stem cuttings (Figure 4(a)). From planting to harvest, cassava has five progressive developmental stages, i.e., emergence of sprouting (5–15 DAP, day after planting), beginning of leaf development and formation of root system (15–90 DAP), development of stems and leaves (90–180 DAP), high carbohydrate translocation to roots (180–300 DAP), and dormancy (300–360 DAP). The development of leaf, which starts from emergence of buds (folded, 1 cm long) and ends when it reaches its full size, usually requires 10–12 days. And the leaf life (from emergence to abscission) is commonly 60–120 days, depending on cultivar, shade level, water deficit, and temperature (Cock, 1984). All cassava organs, except seeds, contain cyanogenic gulcoside (CG). Cultivars with CG <100 mg kg^{-1} fresh weight (FW) are called 'sweet,' whereas cultivars with CG 100–500 mg kg^{-1} FW are 'bitter' cassava. The most abundant CG is linamarin (85%), with lesser amounts of lotaustralin. Total CG concentration depends on cultivars, environmental condition, cultural practices, and plant age (Ngudi *et al.*, 2003). Cassava storage roots have the shortest shelf life of any of the major root crops. Roots are highly perishable and usually become inedible within 24–72 h after harvest, due to a rapid physiological deterioration process in which synthesis of simple phenolic compounds that polymerize occurs, forming blue, brown, and black pigments (Bayoumi *et al.*, 2010).

Temperature influences cassava sprouting, leaf formation and size, storage root formation, and consequently general plant growth. The behavior of cassava under the temperature variations indicates that its growth is favorable under annual

mean temperatures ranging from 25 to 29 °C, but it can tolerate from 16 to 38 °C. At low temperature (<16 °C), sprouting of the stem cutting is delayed and rate of leaf production and dry weight (DW) of total storage roots are decreased. Sprouting is hastened when the temperature increases up to 30 °C but is inhibited with temperatures >37 °C. Because the differences in day length in tropical regions are very small, varying from 10 to 12 h throughout the year, photoperiod may not limit cassava root production in this region (Bolhuis, 1966). Long days increase shoot growth and decrease storage root development, whereas short days promote growth of storage roots and reduce the shoots, without affecting total DW. Cassava is also intercropped with perennial vegetation. Thus, in an associated cropping system, cassava is always subjected to different degrees of shading and low-light intensity in the early stage of development (Okoli and Wilson, 1986).

Cassava is a drought-tolerant crop as it is commonly grown in areas receiving <800 mm rainfall year^{-1} with a dry season of 4–6 months. Growth and yield could be also decreased by prolonged dry periods. The reduction degree in storage root yield depends on the duration of the water deficit and the sensitivity of a particular growth stage to water stress. The critical period for water-deficit effect in cassava is from 1 to 5 MAP (month after planting) – the stage of root initiation and tuberization (Vandegeer *et al.*, 2013). A primary response to water stress is stomatal closure, which decreases photosynthetic CO_2 assimilation and, in turn, growth. When water is available, cassava maintains a high stomatal conductance and can keep internal CO_2 concentration high. As a stress hormone, ABA accumulates in both expanding and mature leaves under water deficit condition but completely reverses in respect of control levels after 1 day of rewatering (Alves and Setter, 2004).

Breeding

Cassava can be propagated either by stem cuttings or by sexual seed, but the most common practice is stem cuttings by farmers for multiplication and planting purposes (**Figure 4(a)**). Unlike sweet potato (*I. batatas*), the cassava root is not a reproductive organ. Propagation from true seed occurs occasionally in farmers' fields. The common breeding approach in cassava is through hybridization among appropriate parents. Cassava is monecious, with female flowers opening 10–14 days before the male ones on the same branch. Self-pollination can occur because male and female flowers on different branches or on different plants of the same genotypes can open simultaneously (Jennings and Iglesias, 2002). Cassava is a cross-pollinated species and seldom gets self-pollinated; it has a slow multiplication rate and the production of botanical seed from crosses is expensive. Seedlings with desirable traits are selected and subsequently propagated clonally. Stem cuttings can only be stored for a limited period of time; planting material requires special phytosanitary management (Ceballos *et al.*, 2012). Overall, cassava breeding is time consuming and inefficient in comparison with other major crops, for example, grains.

Therefore, several new approaches have been taken to address this situation in recent years. Modifications of the breeding scheme have been implemented for a more dynamic recurrent selection system and for obtaining valuable information on the breeding value of parental lines (Ceballos *et al.*, 2004). Biotechnology tools have been adapted to cassava and are currently incorporated in different projects for its genetic improvement. Genome sequence of cassava has been released and is publicly available (Prochnik *et al.*, 2012). A high-density molecular map has been developed, and marker-assisted selection is currently used for key traits. Genetic transformation protocols are available and have been used successfully for the incorporation of different genes (Liu *et al.*, 2011).

To date, major agronomic traits of cassava addressed by breeding include high yield and high starch content, good plant type (tall and no or little branching), early harvest and early bulking capacity, improved nutritional quality, virus resistance, reduced cyanide content, and delayed postharvest physiology deterioration in storage roots. Many farmer-preferred landraces and new-bred cassava cultivars had been widely cultivated in regions. For example, in Nigeria, cultivars TMS 30572, TMS 00/0203, TMS 01/0040, NR 01/0004, and CR 41–10, which are high yielding as well as disease and pest resistant, have been released and adopted in varying degrees in different ecological zones of Nigeria. In Thailand, Kasetsart 50 (KU50), Rayong5, Rayong90, Rayong72 are major new released cassava cultivars in the past decades and the KU50 becomes the most popular cultivated cultivar in the ASEAN countries. In China, SC205 and NZ199 are most popular cultivars for decades, covering more than half of total planting area.

Cultivation

Good cultivation practices are important for increasing cassava productivity. The practice includes variety selection, soil preparation, appropriate time for planting and harvesting, planting techniques, weed and disease control, fertilization, and irrigation.

The soil should be plowed in depth to loosen soil structure and ridge according to terrain before planting, which is advantage for root formation and soil moisture retention. It is suitable for cassava growth under moisture climate and the temperature exceeding 15 °C. Therefore, farmers usually plan the planting date based on natural rainfalls. It is very crucial to employ good cassava varieties with high yield, high resistance to diseases, adaptation to different environment stresses, good plant features, and high stem quality (Ayemou *et al.*, 2011). Planting materials should be free from pests and diseases and had better be taken from plants ranging from 8 to 18 months of age. To prevent dehydration during storage, the harvest stems should be as long as possible before planting. Stem should normally be cut in the range of 15–25 cm in length. The plant spacing is approximately 1.0×1.0 m, which can be more or less, depending on soil fertility and plant branching. It is useful to spray or submerge the stems in a solution with an insecticide and a fungicide before planting (Sriroth *et al.*, 2010). There are three kinds of planting patterns including vertical planting, tilting planting, and horizontal planting. Vertical planting has higher resistance to wind and drought. Tilting planting has the higher sprout rate and horizontal planting is easy for harvest but the resistance is lower. This

constant cropping system can rapidly deplete the soil fertility, so sustainable and productive cropping systems are needed (Örjan, 1993). Intercropping or shifting cultivation is a good choice for cassava productivity, and this method has been widely applied (Staver, 1989). There are several intercropping methods including cassava as principal crop intercropping with short-period crops, perennial woody plants as majority intercropping with cassava, and one kind of crop planted instantly following cassava planting.

Weed and pest control are very critical after planting. Weed should be removed either manually or by chemicals. When chemicals are used, it should be considered that the chemicals do not cause any harm to cassava plants. Basal fertilizer and applying fertilizer in the later period are important for increasing root and top biomass (Cadavid *et al.*, 1998), especially potassium fertilizer. Nitrogen fertilizer is not too much, because it can induce the higher cyanic acid content in storage roots. Sprouting rate was strongly influenced by the N, P, and K contents in the stakes. Stakes from plots with moderate level of N, P, and K application resulted in plants that had the highest roots production in both fertilized and unfertilized soils (Molina and E1-Sharkawy, 1995). Cultivation under a very dry condition can be improved by additional water irrigation. Water-dripping system is currently introduced to some cassava planting areas.

The root can be harvested after 10 months of plantation (**Figure 4(b)**). Harvesting can be delayed or advanced, depending on root prices. Fresh roots harvested in the rainy period usually contain less starch contents. Some stems with good stake quality are reserved for new crop propagation and the rest including other biomass are used for fuel and infield fertilizer. Stems can be stored as they have been harvested from the field. There are different storing methods such as heap storage method in the open, trenching storage method, and cache method.

Diseases and Insects

Cassava cultivation is associated with a wide range of diseases and insect pests that reduce cassava yields substantially, posing a threat to food security throughout the developing world. The rapid geographic expansion of the cassava mosaic disease (CMD) pandemic, caused by cassava mosaic geminiviruses, and outbreaks of cassava brown streak disease (CBSD) from Uganda and other parts of East Africa, caused by potyviruses, have devastated cassava crops in most African countries (Legg *et al.*, 2006). Both of these viral diseases are transmitted by whiteflies (*Bemisia tabaci*). Conventional host plant resistance is the most widely practiced control measure for CMD. High levels of resistance to all cassava mosaic geminiviruses (CMGs, Family Geminiviridae, and Genus Begomovirus) have been developed through conventional breeding programs using two different sources of resistance (Dixon *et al.*, 2003; Hahn *et al.*, 1980) and resistant varieties have been widely deployed in CMD management programs. CBSD is caused by two virus species: Cassava brown streak virus (CBSV) and Ugandan cassava brown streak virus (UCBSV) (picornalike (+) ssRNA viruses, genus Ipomovirus, and family Potyviridae). Contrary to CMD, limited natural resistance to CBSD, in a few cassava genotypes, has been identified and demonstrated for one of the viral species (UCBSV) causing CBSD (Winter *et al.*, 2010). The deployment of CMD-resistant cassava with different levels of susceptibility to viruses causing CBSD continues to impact production and alters the distribution and occurrence of UCBSV and CBSV in the field. Transgenic strategies have been developed to engineer the dual resistance to both viruses and transgenic plants undergoing field trials in several countries in Africa (Zhang *et al.*, 2005; Vanderschuren *et al.*, 2012).

Besides being transmitted by the whitefly, for which numerous invasive species have been described, transmission via human-mediated transport of infected stems is today postulated to play an important role in the spread of CMGs and CBSD. Currently, various CMG and CBSV species are widely distributed throughout Africa (Patil and Fauquet, 2009; Ndunguru *et al.*, 2005) and ongoing monitoring of cassava indicates that some CMG and CBSV species are in the process of expanding their geographic ranges.

The most serious pests of cassava are generally those that have coevolved with the crop, especially the cassava green mite (CGM; *Mononychellus tanajoa*), mealybugs (*Phenacoccus herreni* and *Phenacoccus manihoti*), whitefly (*Aleurotrachelus socialis* and *Aleurotrachelus aepim*), hornworm (*Erinnyis ello*), lacebugs (*Vatiga illudens*), and stemborers (*Chilomina clarkei*) (Bellotti *et al.*, 2012).

Disease- and pest-control practices have physical, chemical, mechanical, and biological controls. A successful integrated pest management (IPM) program in cassava will depend on having effective, environmentally sound, and low-cost pest management technologies available to cassava farmers in developing countries. Biotechnology tools currently available offer the potential to develop improved pest resistant varieties (Duan *et al.*, 2013) and enhance the effectiveness of natural control organisms including parasitoids and entomopathogens.

Economic Importance and Uses

Cassava is one of the most important starch crops, and the storage root is mostly used as a source for food and starch products. The total production of cassava all over the world was approximately 184 million tonnes in 2002 and 250 million tonnes in 2012 (FAO, 2012). In Africa, most of these tuberous roots were consumed locally as main food and very few were exported. In Asia, cassava is mainly used as raw material for feed and starch industry. The major cassava producers are Brazil in South America; Thailand, Indonesia, and India in Asia; and Nigeria and Congo in Africa. Thailand is the biggest exporter in the world. In developing countries, especially in sub-Saharan Africa, cassava plays a particularly important role in food security because of its high tolerance to poor soil and dry season; besides, it has a flexible harvesting schedule (Cock, 1984). The cassava root is rich in calcium and vitamin C and contains a significant quantity of thiamine, riboflavin, and nicotinic acid. Although cassava storage roots contain less protein, the protein content in cassava leaves are high and valuable because they are rich in essential amino acids such as methionine, cysteine, and cystine. Generally,

every part of cassava can be utilized, but the storage root is most commonly used in, for example, food, industry, and biofuels.

Cassava, like other foods, also has antinutritional and toxic factors such as the cyanogenic glucosides, which can release hydrocyanic acid (HCN) by hydrolysis. Cassava must be cooked first in order to detoxify it before it is eaten. However, cassava root is widely processed into variety of dishes and is consumed regionally, nationally, and sometimes ethnically. The soft-boiled and fried cassava root, having a flavor, can substitute for boiled potatoes as an accompaniment for meat dishes in some households. In Brazil, detoxified manioc is ground and cooked to a dry, often hard or crunchy, meal which is used as a condiment, toasted in butter, or eaten alone as a side dish.

Cassava leaves are used as vegetables in some regions of Africa. Overground part of cassava can be used for animal feed as well. The overground part, harvested approximately 30–45 cm at the three- or four-month stage and is dried for one or two days until it is classed as cassava hay. The cassava hay, containing high-level protein (25%) and condensed tannins, can be used as nutrient-rich roughage for animals.

In Thailand and China, cassava is mainly used as raw materials for extracting starch, which can be processed to various modified starches. Besides, cassava is also essential for energy security. Regionally, cassava becomes mostly a source for ethanol production. The increase in demand of cassava starch and nongain derived biofuels has boosted the expansion of cassava cultivation globally.

Rural Sociology

DH Constance, Sam Houston State University, Huntsville, TX, USA

© 2014 Elsevier Inc. All rights reserved.

Glossary

Adoption–diffusion of technology Process by which individual farmers (or other prospective users of technology) make decisions about the use or nonuse of a new technology.

Land grant universities Integrated system of teaching, research, and outreach created to modernize agriculture.

New Rural Sociology Conceptual approach to the sociology of agriculture that embraced critical perspectives of rural development.

Rural–urban continuum Notion that the nature of social structure, social relationships, and values vary systematically across rural and urban communities.

Sociology of agricultural science Study of the process through which scientists and scientific institutions discover new knowledge.

Sociology of agrifood studies Study of the sociology of agriculture and food that links agricultural production and food consumption to globalization and commodity systems.

Introduction

Rural sociology is historically defined as the sociological study of social organization and processes that are characteristic of rural societies and geographical areas where population densities are relatively low. In practice, modern rural sociology is considerably more comprehensive than the study of rural societies. As rural societies do not exist in isolation, rural sociology increasingly addresses the relationships between rural society and society as a whole and within the global economy and society. Vertical linkages to the macrosystem integrate rural areas into national and global social processes (Bonanno *et al.*, 1994; Warren, 1963).

Although rural sociology as a discipline originated in the United States in the early twentieth century, as part of decolonialization and modernization projects after World War II, it has diffused around the world where it is more often referred to as peasant studies, development studies, or village studies instead of rural sociology (Newby, 1980). Additionally, many of the foci of rural sociology are related closely to other social science disciplines including cultural geography, social anthropology, and agricultural economics.

The Roots of American Rural Sociology

Although the field of rural sociology has made major strides in understanding rural social processes, like the parent discipline of sociology, it still has strong roots in the nineteenth-century social thought. A central concern of nineteenth-century theorists was whether village and farm life was morally and socially superior to metropolitan life, and whether rural life would be resilient in the face of urban industrialism. Informed by the Enlightenment and Western rationalism, the classical sociologists Emile Durkheim (1858–1917) and Karl Marx (1818–83) both argued that urban–industrial capitalism and modern technologies and organizational practices were unavoidable and progressive social forces would eventually supplant the residual remnants of backward, preindustrial rural social forms. In contrast, Ferdinand Töennies (1855–1936) viewed urbanization and industrial capitalism that characterized gesellschaft societies as leading to the decline of the pastoral virtues and intimate communal bonds of rural gemeinschaft societies that are necessary for healthy social life. For Töennies and many early rural sociologists, the cities and social relations of industrial capitalism represented the degradation of civilization. Although Max Weber (1864–1920) recognized the dynamism of the social forces of bureaucratization, industrialization, and urbanization that were marginalizing traditional rural societies, he thought that bureaucratization and the industrial revolution, which he referred to as an iron cage, would lead to social movements, political ideologies, and other forms of resistance to these forces of rationalization and uniformity.

Throughout its history, rural sociology has engaged in these nineteenth-century debates over the desirability and resilience of traditional rural social organization. Two general positions have alternated over time and still exist: (1) the view that rural society, owing to its more intimate social bonds, lower incidence of social pathologies, and stronger religious institutions, is socially and morally superior to urban society and therefore deserves to be preserved and (2) the view that traditional rural beliefs, social structures, technologies, practices, and institutions are nostalgic anachronisms of the past and must be modernized for the quality of rural life to be enhanced. Both positions are embedded deeply in Western social thought and continue to inform the discipline and discourses of rural sociology.

The historical roots of rural sociology in America reside in the economic, political, and economic transformation brought about by the industrial revolution that occurred after the Civil War. Though the surge of industrial capitalism brought affluence to many regions in the United States, it also created poverty and inequality in many rural areas. A benchmark publication in the debate between these two views of rural society was Sorokin and Zimmerman's (1929) Principles of Rural–Urban Sociology, which synthesized rural sociological thought of the time and was the summative treatise in the field. Sorokin and Zimmerman's 'rural–urban continuum' perspective drew primarily on Töennies' analysis of how

 doi:10.1016/B978-0-444-52512-3.00253-9

urbanization and industrial capitalism led to the undermining of the primary social bonds of community. Accordingly, the rural sociology research carried out before World War II was largely devoted to rural community studies and tended to present rural life as socially richer and morally superior to urban life.

Agrarian Politics and the Country Life Commission

America's agrarian politics also significantly shaped the trajectory of rural sociology. Though the term 'rural sociology' was not widely used until the 1920s, the first American rural sociological studies were conducted in the 1890s during a decade of populism and agrarian unrest. These pioneering rural sociological studies were initiated by DuBois (1898), a black sociologist on the staff of the US Department of Labor. DuBois' studies emphasized how the postbellum crop-lien system in southern plantation agriculture reinforced black poverty by tying black farmers to the plantation system and subordinating them to the power of the planter class. During this time, studies of agricultural communities in the northeast were also undertaken by F.H. Giddings and associates at Columbia University. In these early days, land grant universities had little or no presence in the scholarship now called rural sociology.

Although the populist critique of industrial capitalism swept through much of rural America during these years, populism did not directly influence early rural sociology. During the first full decade of American sociology, there was widespread suspicion among university administrators and their patrons that sociology should be scrutinized to ensure that it concerned itself with empirical research rather than populist politics. This political environment led most sociologists to distance themselves from radical social theories and movements. There is no indication that any American rural sociologists were active supporters of populism.

Populism's indirect influences on rural sociology, however, were important. The populists' mostly unsuccessful attempts to recruit black farmers into their movement contributed to the questioning of the sharecropping system, the structure of agriculture, and southern rural social structure. Populist radicalism was a major source of concern to urban industrialists who benefited from a socioeconomic system that provided a stable supply of cheap food for their workers. Although William Jennings Bryant's loss in the 1898 presidential election signaled the defeat of populism in electoral politics, fear of a resurgence of populist radicalism remained for more than a decade.

The aim of providing a moderate alternative to populism was integral to the establishment of the Country Life Movement (Danbom, 1979). Founded by industrial and other elites, the Country Life Movement maintained that, contrary to populist assertions, rural social problems were not owing to the negative impacts of industrial capitalism, but rather because of a lack of organization, poor infrastructure, and technological backwardness in rural areas. In 1908, President Theodore Roosevelt recognized this reform movement by appointing a Presidential Commission on County Life, chaired by Liberty Hyde Bailey, dean of Agriculture at Cornell University. The next six decades of American rural sociology were framed by the Country Life Commission Report published in 1909. The report did acknowledge many of the social problems of rural America (e.g., the inequities of the crop-lien system and widespread sharecropping), but its dominant message was that an expanded effort to modernize rural America technologically and socially was integral to improving rural society. The Country Life Commission recommended the establishment of what is now called the Cooperative Extension Service to speed the modernization of rural America. The Cooperative Extension Service (Smith–Lever Act of 1914) completed the land grant college modernization triangle of teaching (Morrell Act of 1862) and research (Hatch Act of 1887).

The Country Life Commission recommended the harnessing of the social sciences, particularly agricultural economics and rural sociology, to support the technological modernization of rural America. Rural sociological studies in land grant colleges of agriculture were critical in helping to remove social barriers to technological modernization and stabilize rural communities. The establishment of rural sociology, however, was slow and uneven, particularly compared with the field of agricultural economics. Only a few land grant colleges – generally the larger ones in the Northeast and Midwest – established major rural sociology programs. Moreover, it was not until the Purnell Act of 1925 that federal funds were available to support rural sociological research. For all practical purposes, the land grant colleges where rural sociology was present in the 1930s are the same 25 or so institutions where rural sociology existed in the early 1990s.

Institutionalizing Rural Sociology

Three other historical factors were crucial in shaping and institutionalizing rural sociology. First, the Great Depression and the New Deal opened up vast opportunities for rural sociological scholarship aimed at rural reform and relief. By the mid-1930s, sociologists in the United States Department of Agriculture (USDA) Bureau of Agricultural Economics (BAE) and other federal agencies had carried out an impressive program of empirical research on rural communities, rural population, and the structure of agriculture and had linked this research with an agenda for far-reaching rural reforms (e.g., reduction of the power of southern landlords, land tenure reform, and encouragement of cooperative forms of production). Second, the course of rural sociology was decisively shaped when in 1936–1937 rural sociologists broke from the American Sociological Society (later the American Sociological Association) to establish the Rural Sociological Society and started their own journal *Rural Sociology*. The organizational break from the larger discipline of sociology led rural sociology to become even more identified with and institutionalized within the land grant and USDA complex. Third, from the late-1930s through the mid-1940s the progressive reformism of the New Deal came under attack by conservative members of the Congress. The crackdown on reformist rural sociology (and agricultural economics) was completed when the BAE was disbanded in 1944. Seminal works on the relationship between the structure of agriculture and quality of life in rural areas carried out by Goldschmidt

(1947) working for the BAE were suppressed. For two decades after the dismantlement of the BAE, the new generations of rural sociologists were dissuaded from embracing the scholarly and political reform orientations of the New Deal rural sociologists. They were encouraged to embrace positivist social science and provide the basic descriptive information about rural people and rural society to help inform policies targeted to rural modernization.

As a result of these changes, the Töennies–Sorokin–Zimmerman perspective of the rural–urban continuum that favored rural over urban social forms declined in prominence as rural sociology was confronted with the Great Depression and rural squalor, and quickly embraced New Deal reformism. During the New Deal period, rural sociology adopted the modernist view that rural society needed the types of legal, social, and structural reforms that were underway in nonrural arenas, such as labor relations, state regulation of economy and society, old age assistance, and so on. This perspective questioned the romantic and nostalgic position that the traditional structures and practices of rural society were necessarily socially desirable. The rural–urban continuum perspective was also undermined empirically by studies showing that community-like primary social bonds persist even within large metropolitan places.

Rural sociology is a disciplinary product of these historical events interpreted from the two contradictory views of rural society grounded in social theory. The institutional separation from the parent discipline of sociology, the institutional housing of rural sociology programs in colleges of agriculture, and the structural linkages to the Extension Service shifted rural sociology from its original focus on preserving rural life in the face of industrial capitalism to facilitating technologically driven modernization. To survive in the institutional environment of the times, rural sociology embraced its function within the land grant college system by facilitating the modernization of rural society. As politicians and college of agriculture administrators pushed rural sociology to be useful in solving the practical problems of rural society, it lost its preservationist agenda informed by critical social theories. Research that contradicted the prevailing modernist agenda might threaten its institutional standing. By the 1940s, the function and practice of rural sociology was clear, to explicitly support the social policy of transforming rural society through enhanced adoption of modern technologies (Newby, 1980).

Modernist and Preservationist Perspectives

The modernist perspective dominated until the 1960s when rural sociologists and rural advocates began to document and criticize the negative impacts of unquestioned technological adoption as the only path that improved the rural quality of life. The rural–urban continuum perspective reappeared as advocates of rural society renewed their search for ways to preserve what they perceived to be the superior qualities of rural life in the face of the continued spread of industrial capitalism. Their concerns included community disintegration, rural out-migration, loss of local autonomy, family-farm decline, degradation of the rural landscape, and depletion of natural resources. Rural protagonists were informed by the Jeffersonian agrarian values of community, individualism, family-based businesses, and grass-roots democracy (Gilbert, 1982). As noted at the outset of this article, American rural sociology has oscillated between these polar views and agendas of (1) providing uncritical positivist science in support of modernizing backward remnants of preindustrial societies and (2) preserving the special aspects of rural society that support community well-being and enhanced quality of life. Many politicians, land grant university administrators, and advocates of technological innovations still view the preservationist agenda as a major barrier to progress for rural societies.

Though rural sociological research, teaching, and outreach are now undertaken in many nations with rural sociology professional societies on all continents, rural sociology is essentially an American phenomenon. The disciplinary category 'rural sociology' was created in association with the American land grant university system and even today most professional rural sociologists in the United States are still university faculty appointed in land grant colleges of agriculture. The land grant university system was created by the federal government to modernize agriculture and rural life. Though many other countries have a tradition of scholarship similar to rural sociology, the global spread of rural sociology was due mainly to the missionary zeal of rural sociologists from the 1940s through the 1960s, who embraced the modernization perspective. Mostly funded through the rapid expansion of American foreign aid in the post-World War II period, many famous American rural sociologists traveled extensively and diffused American-style rural sociology across a wide range of countries, often helping to create land grant-style systems. As late as the 1960s, rural sociology in other countries was very similar to the American variety.

Beginning in the 1970s, rural sociology became increasingly diverse. Today US rural sociology is not nearly so homogeneous or globally influential as it once was but increasingly borrows from the ideas of European and developing world scholars. Although the modernization perspective is still prominent, the reengagement with critical perspectives has expanded as positivist interpretations were found lacking in explaining social change. Continental and regional professional rural sociology societies, such as the Latin American Rural Sociological Association, European Society for Rural Sociology, Australia and Oceana Network, and Asia Rural Sociological Association as well as the International Rural Sociological Association have expanded. Rural sociologists are active in many of the research committees of the International Sociological Association. The dominance of the land grant university model in the United States has also waned. Owing to a combination of budget cuts, mission redefinition, and academic reorganizations, during the last two decades several rural sociology programs at land grant universities have closed or merged into broader social science programs. As a result, rural sociologists are increasingly employed in non-land grant university settings in the public and private sectors.

The Major Foci of Rural Sociology

Modern rural sociology has six major branches of study: rural population, rural community, rural social stratification,

natural resources and environment, agriculture and food, and science and technology. Following the dichotomous pattern presented in the Section Modernist and Preservationist Perspectives, some branches of study emerged and developed during the historical periods dominated by modernist perspectives and other branches during times informed by critical perspectives. In this article, principal attention is given to science and technology and agriculture and food. Before doing so, a brief description of each of the major specialties in American rural sociology is provided. This section concludes with a discussion on international rural sociology.

Population and Community

From the inception of rural sociology, sociological analysis of rural population and rural community dynamics through census and social survey data has been central to the field. DuBois' early work on black farming was largely based on population census data. As will be dealt in more depth later, the overarching frame of all early rural sociological research is the sociology of agriculture. Patterns of farming systems were studied to try to better understand the relationship between types of farming operations and quality of life in rural areas. Recall that DuBois' early work was on the implications of the Black tenant sharecroppers and planter landlords system of agriculture in the south. The methodology of these early studies was usually the community survey, which cemented the overlap between population and community studies. The Country Life Commission report noted the lack of and need for complete and accurate information regarding the conditions of rural life. The work of the Division of Farm Population and Rural Life of the BAE provided basic descriptive data about the rural population and established rural population studies as one of the pillars of the field. These early descriptive studies generated typologies of farming systems that were used to inform modernization programs carried out by the Cooperative Extension Service, which had an office in nearly every rural county in the United States. Major rural sociology programs included a specialist in rural population and rural community studies who analyzed census data for counties and rural places. Population studies still provide the important basic descriptive information used to inform the policies and programs designed to modernize rural society (Garkovich, 1989).

Rural population and community studies have become increasingly differentiated so that they are now seen as distinct specialties. Rural population research has followed demography in becoming more quantitative and descriptive. Studies that have moved past description into more sociological investigations tended to be guided by the human ecology perspective (Hawley, 1950). Although Hawley's systems model does incorporate the interplay between population, organization, environment, and technology variables and therefore allows for a more sophisticated evaluation than the empirical description of demography, its ability to integrate the spatial with the social aspects of rural society is limited. As population studies and demography generated a wealth of data on both rural and urban populations, it became possible to conduct statistical comparisons between the two groups and thereby test some of the preservationist propositions that population size and density influence social actions and organization; the greater the size and density the lower the social cohesion and quality of life. As noted in the Section The Roots of American Rural Sociology, this frame was first conceptualized as the Töennies–Sorokin–Zimmerman rural–urban continuum and later as the 'folk-urban continuum' (Redfield, 1947). The evidence of a linear relationship that shows decreased quality of life associated with increased population size and density has been mixed. Gemeinschaft relationships were discovered surviving within gesellschaft communities. As a result, the use of census data to document rural–urban differences has been discarded by most rural sociologists.

The rural sociological analysis of communities can be traced back to Galpin's (1915, 1918) pioneering holistic community studies. Galpin is known as the founder of rural sociology. At the University of Wisconsin, Galpin initiated rural life studies based on community studies. His study titled 'The Social Anatomy of an Agricultural Community' was the first Experimental Station bulletin in rural sociology. Galpin was also very active in the American Country Life Association, and later headed the Division of Farm Population and Rural Life in the BAE/USDA. Rural sociologists have conducted thousands of community studies in support of community developed policies and programs (Summers, 1986; Wilkinson, 1991).

By the 1960s, the criticisms of the rural–urban continuum approach for being weak methodologically and excessively descriptive had solidified (Bell and Newby, 1972). Community studies suffered from the advance of the mass-society thesis, which argued that local communities have been eclipsed by the macrosystem forces of industrialization, urbanization, and bureaucratization (Stein, 1964). Through increased vertical linkages, extralocal forces overwhelmed the horizontal linkages of local communities and rendered small rural communities powerless (Warren, 1963). Later research found that increased vertical linkages do not necessarily destroy horizontal linkages, which tempered the macrosystem dominance thesis (Summers, 1986). Much of the community studies work done today employs either the social capital perspective (Flora and Flora, 2008) or the interactional field perspective (Wilkinson, 1991).

Social Stratification

Throughout human history, there has been a tendency for poverty, disadvantage, and political subordination to be exhibited disproportionately among rural people. Preindustrial rural social structures (e.g., feudalism, the antebellum and postbellum Southern plantation systems in the United States, landlord-dominated rural economies in much of South and Southeast Asia, and the latifundia–minifundia complex of Latin America) tended to generate social inequality. In modern societies, rural people have tended to be poorer than urban people. The equation of rural with poverty and inequality has made analyses of rural social stratification and inequality an important dimension of rural sociology. The substantive area of rural social stratification has a long and controversial history

in rural sociology. DuBois' work on tenancy in the south revealed patterns of race-based institutional discrimination. Populist concerns over the power of the agribusiness trusts triggered a broad-based social movement critical of the impact of industrial capitalism on rural society. Cognizant of these expressed concerns regarding inequality, administrators of turn-of-the-century universities steered sociological attention away from controversial class and other inequalities and toward perspectives, such as population analysis and the rural–urban continuum. Thirty years later the New Deal climate of state-led reformism created space for rural sociological attention to social class, race, and poverty, though this space shrank as the New Deal was rolled back, the BAE was dismantled, and Cold War intensified.

Rural social stratification and related analyses enjoyed a renaissance during the Great Society Era and War on Poverty in the 1960s. The study of rural social stratification continues to be a lively and increasingly more diversified arena of inquiry. Studies of regional and labor market inequalities, rural gender inequality, and rural racial inequality have enriched the analysis of rural social inequality (Lobao *et al.*, 2007). These analyses have been extended to the global level and to metropolitan-corporate forces, such as international competition among private multinational agricultural input firms as part of the globalization of economy and society (Bonanno *et al.*, 1994; McMichael, 1994).

In the 1980s, rural labor market studies emerged to analyze the changing economic base and employment opportunities in rural America. Modernization and mechanization of agriculture and other extractive natural resource-based industries supported the steady decline of employment in the primary sector of the economy. From the modernization perspective, rural to urban migration was a natural outcome of the efficiencies gained when capital replaced labor. In the 1970s, rural areas experienced a manufacturing boom as industries migrated south from the rust belt in search of cheaper land, lower taxes, and nonunion workers. Although this trend continues as major manufacturing companies shop for rural locations to site their operations, service industries have emerged as the major source of employment growth. These shifts have contributed to uneven employment opportunities, high unemployment in many rural regions, the growth of temporary, part-time, and informal work, and often increases in poverty. Much of the research investigates the nature and extent of rural unemployment and underemployment, with a growing focus on the linkages of rural labor markets to the macroprocesses of national economic restructuring as part of the globalization of economy and society (Green, 2007; Tigges and Tootle, 1990).

Gender studies in rural sociology received little attention until the late twentieth century (Haney and Knowles, 1988). Since then numerous studies have been carried out that investigate how the institutions of capitalism and patriarchy influence the work roles of men and women in the home, on the farm, and in other rural labor markets. A major dimension of these studies is the nature of farm women's household, farm, and off-farm work (Sachs, 1996). Recent research has revealed the hidden and mostly unreported contributions of women to rural sociology (Zimmerman and Larson, 2010). Gender studies have also started to focus on the topic of farm men and issues of masculinity (Campbell *et al.*, 2006).

Natural Resources and Environment

There is an established tradition of rural sociological scholarship on the relations between people, communities, and natural resources. This scholarship is divided theoretically and methodologically into the sociology of natural resources (SNR) and environmental sociology (ES) camps (Buttel, 2002). These camps mostly followed the two perspectives noted in the Section Modernist and Preservationist Perspectives. The SNR camp is grounded in early twentieth-century discussions regarding conservationist (forester Gifford Pinchot) versus preservationist (ecologist John Muir) views of natural resources. It focuses on conservationist approaches regarding efficient management of nonrenewable and renewable resources with a strong applied and empirical orientation (Field and Burch, 1988). By the 1960s, the SNR was an established research area made up of a combination of (1) social scientists employed in government natural resource management agencies, such as the US Park Service, US Forest Service, Bureau of Land Management, and Corps of Engineers; (2) scholars working in the areas of leisure and recreation studies; and (3) rural sociologists working on resource-dependent community issues, such as the boomtown phenomenon of mining and forestry communities. In the 1970s, the field expanded to include the area of social impact assessment. Most SNR researchers are employed in private or public resource management agencies or natural resource-related academic departments, such as forestry, wildlife and range management, fisheries, or international development. SNR researchers are often members of the International Symposium on Society and Resource Management and publish in the flagship journal, *Society and Natural Resources*.

The substantive area of ES emerged in the 1960s and 1970s as part of the environmental movement (Buttel, 2002). Most early environmental sociologists were academics at liberal arts institutions with a substantive interest in environmentalism. Although some of the environmental sociologists had backgrounds in natural resource sociology and then expanded their research arena as environmental externalities and concerns manifested in the 1960s, most were younger academics with a strong commitment to environmentalism. The original research questions focused on the characteristics of environmentalism and the structure of the environmental movement, then expanded to the areas of pollution and resource scarcity owing to industrial production and consumption (Bell, 1998; Buttel, 1978; Catton and Dunlap, 1978; Schnaiberg and Gould, 1994).

ES approaches tend to be more critical and address the 'Environmental Question' regarding the relationship between modern agriculture and environmental quality. More radical neo-Marxist interpretations (O'Connor, 1998) argue that capitalism is inherently contradictory with ecological sustainability, whereas less radical perspectives such as reflexive modernization (Beck, 1992) support reformist agendas such as green technologies. In the past two decades, the field of political ecology, mostly advanced by critical geographers and development social scientists, emerged as a complement to ES (Peet and Watts, 1996). Rural sociology was at the leading edge of the larger subdiscipline of ES and continues to provide strong leadership in applied areas of ES (Freudenburg, 1986; Dunlap *et al.*, 2002).

International Rural Sociology

As noted earlier, many of the prominent American rural sociologists of the post-World War II period encouraged the global diffusion of rural sociology, particularly in the developing world. The impulse for diffusing international rural sociology (or the sociology of development) was partly the desire to promote a comparative approach to understanding rural social organization, but more importantly the post-War period was an emerging era of 'developmentalism,' based on a faith in the efficacy of scientifically planned social change and technological development in the decolonizing world. Rural sociologists thought they had a great deal to offer for improving the quality of life in the developing world. Rural sociologists trained in the adoption and diffusion of agricultural technology (see Section Rural Sociology and the Diffusion Era) were well represented among these early international rural sociologists. The Cold War dynamic accelerated the push to diffuse the technological answer to hunger and development and combat the spread of communism. Food aid such as PL480 was a major dimension of these development assistance programs. Modernizationist interpretations of PL480 viewed it as improving the Third World's diets, whereas critical interpretations viewed it as neocolonialism and cultural imperialism of Western diets (McMichael, 1996).

This modernizationist/developmentalist tradition of rural sociology held firm for nearly three decades, but ultimately was displaced intellectually by critiques for its lack of efficacy and of having ignored how development is constrained and blocked by the global and national dynamics of the international political economy, as well as the ethnocentrist imposition of one culture upon another. This early tradition of international rural sociology would be undermined, in particular, through critical assessments by rural sociologists regarding their participation and the role of rural sociology in the Green Revolution (Flora, 1990; Havens and Flinn, 1975).

The sociology of international rural development has contributed substantially to the development of rural sociology as a whole. International rural sociological studies have helped to temper the tendency for this discipline embedded in the land grant system to become parochial. International rural sociology scholarship has also contributed to important theoretical trends in the field. For example, the late 1970s is regarded as a period of ascendance of the 'New Rural Sociology,' whose principal theoretical underpinnings were grounded in the critique of international development programs and the role of developmentalist/modernizationist rural sociology in contributing to these programs (Buttle and Newby, 1980). This critical literature became known as the dependency theory (dependista) critique (Gunder Frank, 1969; Wallerstein, 1974) of the great modernization project (Parsons, 1966; Rostow, 1960). In the 1990s, the Wageningen School (Long and Long, 1992; Van der Ploeg, 1992) introduced actor–network theory (ANT) and a social anthropology approach to rural lifestyle studies. ANT provided an interpretive alternative to political economy perspectives, which dominated the New Rural Sociology in the United States.

In the early 1990s, three major social forces combined to alter the future of international rural sociology. First, land grant universities faced with growing fiscal pressures cut their international development program budgets. Second, a crisis of confidence in the ability of development intervention programs, such as the World Bank (WB), the International Monetary Fund (IMF), and the US Agency for International Development to make positive differences in the developing world ensued as the global recession of the 1980s, international mobility of finance and industry linked to the globalization of economy and society, and imposition of structural adjustment programs on debtor countries threatened the possibility of balanced growth in the developing world. The 1990s was the 'postdevelopmentalist' era in which the faith that meaningful planned development based on positivist approaches could occur waned as the harsh realities of globalization and fiscal austerity associated with the late twentieth century political economy became apparent. Third, the fiscal crisis of the state combined with the demise of the USSR as a global threat created a significant decline in the US development assistance programs, which had traditionally been the major source of funding for international development sociology (McMichael, 1996).

Rural Sociology and the Diffusion Era

Embracing the adoption and diffusion of technology perspective was a pivotal turn in the development of rural sociology (Fliegel, 1993). It dominated the rural sociological scholarship during the 1950s and 1960s. Before this shift the rural population, community studies, and rural–urban continuum traditions prevailed. Attention to technological change had been confined to a few studies, such as Williams' (1939) work on the impact of the mechanization of cotton production on field labor in the plantation systems of the south. Even during the height of diffusion research in rural sociology, the labor dislocations caused by mechanization of southern agriculture led many rural sociologists in the region to question the implications of new technologies.

The adoption–diffusion perspective is a social–psychological approach that explains why farmers adopt new technologies (Rogers, 1962). Farmers are social actors with different cognitive states due to variation in education and other factors and various value orientations, such as different levels of modernity, innovativeness, and risk-taking. Farmers respond to stimuli, such as the characteristics of new agricultural technologies, mass media messages, and influences from reference groups. Unlike the earlier traditions in which community was stressed, the adoption–diffusion perspective deemphasized the spatial aspect of rural society and focused on particular psychological traits of individuals (Fliegel, 1993).

The rise of the adoption–diffusion perspective was an outcome of many trends of the time. The rural–urban continuum perspective was exhausted and its role in data reconnaissance to support New Deal reforms had waned. In the 1940s, there was much excitement about hybrid corn and the pioneering adoption studies focused on this technology. It identified which farmers had the highest rates of adoption of hybrid corn and how the innovation was diffused to other farmers. The social climate of the time was conducive to shifting rural sociology to a focus on technologically driven

modernization of rural society as the best path to improved quality of life. Adoption–diffusion studies were also a strategic way to make rural sociological research useful to experiment station directors in the post-BAE climate. And in sociology at large, the 1940s was a period of increased emphasis on social psychology and survey research, which were integral to adoption–diffusion research. Adoption–diffusion advocates believed they had the answer to humanity's ills and the scientific method to diffuse the answer. In agriculture, the promise was to end hunger and generate development.

The adoption tradition produced a number of generalizations about the process of agricultural technology diffusion. For example, it was repeatedly found that plots of cumulative adoption over time took the form of a logistical growth (or 'S') curve where adoption by the innovators proceeded slowly, then accelerated through the early and late adopters, then decelerated again as some of the laggards finally adopted. Earlier adopters of new technology tended to be younger, have higher levels of education, and to have more 'modern' value orientations than do later or nonadopters. Research also revealed that correlations between farm size and farm household wealth and adoption of new commercial innovations tended to increase over time. Soon adoption–diffusion research spread to other innovations and countries as part of the modernization era (Fliegel, 1993).

Critics stressed that a shortcoming of adoption–diffusion was that it viewed new technologies as unambiguous improvements. Farmers who did not adopt were referred to as 'laggards.' Adoption researchers seldom considered how technologies might affect the structure of agriculture or the environment. Despite the utility of the adoption–diffusion perspective, its influence began to decline in the late 1960s and early 1970s in tandem with a growing skepticism toward modern agricultural technologies among sociologists and society at large. Although adoption–diffusion research no longer has the prominent position it once enjoyed, modified diffusion theories and methodologies still enhance the understanding of the processes of technological change.

The New Rural Sociology

By the 1960s, the critique of positivist frameworks that supported the unquestioned adoption of technology as the panacea for rural society was well established. Critical rural sociologists were concerned that social theory and research had been decoupled and that the uncritical empiricism of adoption–diffusion approaches generated unacceptable externalities for rural environments and rural people. Several rural sociologists with experience in adoption–diffusion programs internationally challenged the Western orthodoxy of the technological panacea by arguing that modernization served the interests of the wealthy elites and business interests to the detriment of peasants and poor people (Havens, 1972). In North America and Europe similar discontents emerged as social movements claimed that environmental degradation and institutional discrimination persisted. The normative and positivist conceptual frameworks that dominated for the previous 20 years could not explain the social unrest of the time. Rural social scientists turned to critical perspectives to better explain why the public policies and programs of the federally sponsored land grant university system which claimed to be improving the quality of life for rural people was working well for some groups but marginalizing other groups. This shift in theoretical focus generated what is called The New Rural Sociology (Buttle and Newby, 1980).

It was noted at the outset of this article that rural sociology's history has been one of alternating between opposing views regarding the distinctiveness of traditional rural social structures. Rural sociology came into its own during the post-World War II era. Post-War rural sociology tended to reject the rural romanticism of the 1920s and embraced the technological-modernizationist paradigm that traditional rural social structures were destined to disappear, that there was nothing intrinsic to rural America that was sufficiently socially or morally superior to make it worthy of preservation, and that technological modernization was the most desirable future for rural America. In the 1970s and early 1980s, the pendulum began to swing back toward the rural preservationist perspective. Emerging controversies over agricultural technologies and their social and environmental impacts tarnished the luster from the technological-modernizationist view. The 1970s were a period of 'rural renaissance' because of metro-to-nonmetro migration and a stabilization of the declines in farm numbers that characterized the post-War period.

The New Rural Sociology that emerged during the 1970s and 1980s was decisively shaped by several phenomena in the larger society. Five interrelated social movements are noteworthy: Hightower's (1973) critique of the land grant university system linked to mechanization technologies; the 1970s critique of the Green Revolution; public resistance to the rise of biotechnology in the 1980s; the sustainable agriculture movement in the 1980s; and the rise of global environmentalism in the 1980s. Social scientists placed emphasis on explaining the origins of these movements and how they shaped research policies and the content of new technologies. Most importantly, disagreements over new technologies in society at large prompted social scientists to ponder whether there are intellectually rigorous and socially constructive ways to take a neutral and detached position toward the practice of science and the development of new technologies.

These new realities of rural America combined with the growing popularity in sociology of critical theories led to the New Rural Sociology. Adoption–diffusion approaches grounded in positivistic assumptions of social change did not explain well the societal conflict in the times. These new theories ranged from various forms of neo-Marxism and neo-Weberianism to critical theories drawn from hermeneutics and related traditions. The coherence among these theories was their common critique of modernizationist rural sociology. The dominant theoretical underpinning of the New Rural Sociology drew heavily on neo-Marxist interpretations of the social differentiation in agriculture, including the central role of the state and powerful interest groups in maintaining the political-economic system. The farm/debt crisis of the 1980s provided the empirical setting to apply the New Rural Sociology framework. 'Save the Family Farm' was a familiar rallying cry for populist movements, such as Prairie Fire, the American Agriculture Movement, the Center for Rural Affairs (CRA, 2013), and the National Farmers' Union (NFU, 2013).

The critical New Rural Sociology first focused on the paradox of the persistence of a majority of small family-based producers that produced a small percentage of farm output combined with the growth of large, capitalist operations that accounted for large shares of production. The 'Agrarian Question' was rediscovered as rural sociologists asked, 'What is the relationship between the structure of agriculture and the quality of life in rural communities?' Goldschmidt's (1947) work from California on the negative relationship between community quality of life and industrial agriculture was rediscovered. The early discussions centered on how capitalist relations of production penetrated agriculture, including the barriers to agricultural industrialization. The sociology of agriculture emerged as a distinct substantive area within rural sociology (Buttel *et al.*, 1990).

At the international level, the New Rural Sociology represented a major shift away from positivist adoption–diffusion approaches to critical world systems and dependency conceptual frames. Much of the critique of adoption–diffusion came from those international rural social scientists who did research in the developing world and who realized its faults as a tool for understanding agricultural change in rural areas (Havens and Flinn, 1975; George, 1976; Lipton, 1977). Discussion centered on terms, such as Gunde Frank's (1969) 'the development of underdevelopment' and Wallerstein's (1974) 'world system' of core, semiperiphery, and periphery counties structured in unequal exchange relationships as a remnant of colonialism. In the 1990s, the New Rural Sociology combined the domestic and international foci to incorporate commodity systems (Friedland, 1984) and commodity chain analysis (Hopkins and Wallerstein, 1986), which documented the political-economic dimensions of globalization of agriculture and food systems (Bonanno *et al.*, 1994; McMichael, 1994; Goodman and Watts, 1997). Though the New Rural Sociology was most prominent in the sociology of agriculture literature (see Section Sociology of Agriculture and Food Studies), it had a major influence on the rural sociological study of agricultural science and technology as well.

The Sociology of Agricultural Science

In the post-Hightower period rural sociologists were unable to develop a distinctly sociological theory of technological change, so they build upon the 'treadmill of technology' concept from agricultural economist Cochrane (1979). Proceeding from an adoption–diffusion perspective, Cochrane's theory noted that earlier adopters received innovator's rents because of increased production combined with lower per unit production costs. However, because new technologies increase production and agricultural commodities have low price and income elasticities of demand, overproduction and declining commodity prices ensue. Depressed prices negate innovator's rent and force nonadopters to adopt, get on the treadmill, or go out of business. Nonadopter's lands were then consolidated into the early adopter's operations (cannibalism), increasing farm size. Cochrane commented that the treadmill was subsidized by government commodity programs, which placed a floor under commodity prices. These subsidies caused the benefits of new technologies to become capitalized in the farm asset values of the surviving large landowners.

Rural sociologists appropriated Cochrane's account of technological change but soon found it to be lacking for a number of reasons. The treadmill theory is more valid when analyzing family farming systems compared with large-scale industrial agriculture. It also exaggerates the structural nature of technological change in family-farm agricultures. As most family farmers have significant off-farm work, they have more autonomy concerning adoption decisions. The technology treadmill perspective's focus on mechanization technology applied better to the 1950s than the 1980s agriculture. Furthermore, treadmill of technology reasoning does not address the origins of new technologies, a limitation that was addressed by the development of a rural sociology of agricultural science.

As noted in the Section Agrarian Politics and the Country Life Commission, there were significant studies of technological change and labor displacement in southern plantation agriculture. The sociological study of the diffusion of agricultural innovations began during World War II. Until the late 1960s, the adoption–diffusion perspective was the most important area of rural sociological research. However, the diffusion tradition tended to ignore the social origins of science and technology and the social consequences of technology. The functionalist assumptions of adoption–diffusion approaches minimized the political–economic dimension of rural sociological research. Serious study of the processes by which agricultural science is practiced and new agricultural technologies are developed did not emerge until Lawrence Busch and William Lacy began to draw from the sociology of science to develop the field of the sociology of agricultural science. During the 1980s, a prominent group of rural sociologists, including Busch and Lacy (1983), Friedland (Friedland *et al.*, 1981), Geisler (Berardi and Geisler, 1984), and others created the sociological study of the social consequences of agricultural technology.

An important breakthrough in rural sociological thought occurred when Busch and Lacy grappled with how rural sociology could meaningfully engage public debates over agricultural research and technology. They recognized that critiques of technology needed to demonstrate that there are meaningful technological alternatives and that a change in the structure of research institutions or research policy can affect the content and impacts of new technology. To understand whether there are alternatives to existing or emerging technologies, science and research needs to be studied rather than just the social impacts of technology. Busch and Lacy pioneered the field of the sociology of agricultural science with their theoretical critique of the implicit sociology of science and knowledge within the adoption–diffusion tradition and the application of the sociological theory of influence on the research of agricultural scientists. Their seminal book, Science, Agriculture, and the Politics of Research (Busch and Lacy, 1983), demonstrated the important impacts that scientists' social backgrounds (e.g., farm vs. nonfarm) and institutional nexus (State Agricultural Experiment Stations vs. Agricultural Research Service) have on the research goals of scientists. It documented the fact that science is a social product, and that social factors help to determine which of the several alternative

priorities and approaches are stressed in scientific institutions. Their work provided a way for rural sociology to find some middle ground between unrealistic Hightower-style criticism of new technology on one hand, and uncompromising defense of land grant technology on the other. They contributed to a better understanding of how land grant and other public agricultural research institutions function and helped to galvanize rural sociological interest in contributing to public research policy.

It is notable that their work coincided with the growing interest in the conflict over agricultural biotechnology. They provided a general theoretical and empirical template for the numerous studies that would be done to explain the course of the development of agricultural biotechnology. Their own book on biotechnology provides an innovative theoretical position, which combines the insights of ANT from the sociology of science and induced innovation theory from economics (Busch *et al.*, 1991). Busch's work became increasingly informed by science and technology studies (Latour, 1987), which investigates the study of how science is made rather than the finished science. These interests led to his creation of the Michigan State University School of Agrifood Governance and Technoscience (Konefal and Hatanaka, 2010), where his students carried on this research agenda focusing on the scientific production of standards and resulting societal governance by standards. Following the ANT framework, standards are nonhuman actors that structure society in nondemocratic ways. Busch continues to be concerned with the negative impacts that scientism, statism, and marketism have for substantive forms of democracy (Busch, 2000, 2011).

Rural sociological studies of biotechnology are wide ranging. Some of these were aimed at placing modern biotechnology in a historical context of the changing division of labor between the state and private capital in developing and promoting new technology. Other scholars have stressed the new political–economic environment of biotechnology (e.g., new intellectual property restrictions, such as patents), the importance of intellectual competition in biotechnology, and how modern biotechnology could be expected to alter the dynamics of agrarian change in developed and developing countries (Buttel, 2005; Goodman *et al.*, 1987; Kloppenburg, 1988). The fierce controversy over GMO (genetically modified organism) food is a good example of the continuing tension between positivist and critical theoretical positions of the implications of agricultural technology (see the movie Food Inc. (Kenner, 2009)).

Rural sociologists have also pioneered in studies of several areas of agricultural science other than biotechnology, such as developing methodologies for 'commodity systems analysis' (Friedland, 1984). These studies have demonstrated that the forces that shape public and private agricultural research are, more often than not, relatively specific to the commodity sector involved. Another important area of research has concerned sustainable agriculture, which has included research aimed at facilitating agricultural sustainability as well as research on the origins and implications of the sustainable agriculture movement (Allen, 2005; Buttel, 1997). The sociology of agricultural science embraced a critical perspective to study the social significance of the research apparatus of the land grant university system itself, particularly as to whether it has essentially served as a state policy that helped to underwrite the growth of large-scale capitalist agriculture (Rudy *et al.*, 2007).

Sociology of Agriculture and Food Studies

The sociology of agriculture and food is the dominant substantive research area in rural sociology. As noted in the Section Modernist and Preservationist Perspectives, all of rural sociology can be contexted within the original concerns with the relationship between the structure of agriculture and the quality of life in rural communities. The New Rural Sociology represented a significant critical departure from the adoption–diffusion models that embraced positivist models of development. The initial and central problematic of the New Rural Sociology was the 'Agrarian Question' (Buttle and Newby, 1980), which centered on the subsumption/survival debate regarding how capitalism penetrates agriculture and the degree of farmer/peasant integration into industrial agricultural forms. National and international data not only revealed a steady depeasantization of rural areas but also showed that family-farm/peasant operations persisted in the face of industrialization. Rural sociologists were interested in whether family-farm/peasant agriculture would be subsumed into industrial models or if and why it might survive. Three perspectives emerged to explain this phenomenon: the seasonal nature of agriculture and associated biological constraints created barriers to capitalist penetration (Mann, 1990); detours around these barriers, such as debt, contract integration, market concentration, substitutionism, and appropriationism provide other avenues of penetration (Mooney, 1988; Goodman *et al.*, 1987); and petty-commodity producers survive through flexibility and self-exploitation (Friedmann, 1978). The outcome of this debate revealed that structuralist-Marxist interpretations of the demise of family/peasant agriculture were flawed due to particular configurations of family/peasant farming and that historical and spatial contingencies created alternative structures of agriculture (Marsden, 1989).

In the 1990s, the sociology of agriculture and food experienced two significant shifts: agroindustrial globalization and farming styles. The agroindustrial globalization approach argues that the primary drivers of agricultural change reside outside production agriculture and in the areas of national political–economic processes, the global economy, and geopolitics. In particular, the rising power of agribusiness transnational corporations (TNCs) and supranational forms of the state (e.g., IMF, WB, World Trade Organization) as major coordinators of the agrifood system became a crucial research arena. Friedmann and McMichael (1989) introduced the regimes approach from the French Regulationist School to interpret broad historical shifts in global agricultural arrangements. Regimes analysis looks at clusters of symbiotic factors that generate stable periods of capital accumulation interspersed with periods of crisis. The settler regime (Frontier) of the late 1800s dominated by the British Empire was replaced in the 1940s by the agricultural surplus regime (Fordist) dominated by the United States. Institutional crises of the 1970s prompted the end of the surplus regime and the nascent

emergence of the neoliberal regime (Post-Fordism) based on flexible accumulation strategies employed by TNCs who exercised global sourcing strategies to obtain the best factors of production, often to the detriment of subordinate groups and substantive forms of democracy (Bonanno and Constance, 2008; Burch and Lawrence, 2007; Campbell and Dixon, 2009; Heffernan, 2000; Magdoff *et al.*, 2000). The combination of food regimes theory with commodity systems analysis (Friedland, 1984) provided the terminology and framework that informed agrifood theory in the 1990s. Critiques of the neo-Marxist foundations of the agroindustrialization thesis (Goodman and Watts, 1994) grounded in social constructivist perspectives pushed agrifood theory beyond its structuralist and pessimistic outlook. As a result of these events, the sociology of agriculture expanded beyond production and the farm gate to include the global dimensions of complex commodity systems that linked global producers and consumers in shifting commodity chains.

The farming styles approach is often referred to as the Wageningen School based at Wageningen University in the Netherlands. The Wageningen School employs a neo-Weberian actor-oriented approach, which criticizes both functionalist and Marxist approaches for ignoring the relevance of social agency. From this social constructivist view, diverse rural cultures interact with diverse national environments and economies to create diverse farming styles. This diversity of farming styles based on locale-specific farming structures, technologies, rationalities, and practices mitigate the homogenizing forces of the globalization (Arce and Marsden, 1993; Long and Long, 1992; Van der Ploeg, 1992, 2009).

During the late 1990s, the 'Food Question' came to the fore and the substantive research area became known as the sociology of agrifood studies. The 'Food Question' investigates the relationship between the modern agrifood system and the quality of food. Commodity systems and globalization had taken the research beyond the farm gate to include how consumers were drivers of the agrifood system. Goodman's (2003) 'quality turn' captured the growing interest in alternative agrifood systems, such as food sheds (Kloppenburg *et al.*, 1996), regional food systems (Garrett and Feenstra, 1999), community-supported agriculture (DeLind, 2002), slow food (Miele and Murdoch, 2002), organics (Guthman, 2004), civic agriculture (Lyson, 2004), appellations (Barham, 2007), and agriculture of the middle (Lyson *et al.*, 2008). The legitimation crisis regarding both the environmental and socioeconomic externalities of conventional, chemical-intensive, monoculture agriculture, such as poor nutrition, obesity, *Escherichia coli*, *Salmonella*, pesticide contamination, confined animal feeding operations, animal welfare, and systematic rural depopulation had reached critical mass (Wright and Middendorf, 2008). Consumers were driving the agrifood system toward quality instead of commodity foods and researchers shifted their energies from the problems to the solutions of the agrifood system (Hinrichs and Lyson, 2007; The Meatrix (Fox and Sachs, 2003); Grocery Store Wars (Organic Trade Association (OTA) (2005)); King Corn (Woolf *et al.*, 2007); 3 Lies About Food You're Used to Hearing and Might Even Believe (Food Mythbusters and Lappe, 2013); Super Size Me (Spurlock, 2004); and Fast Food Nation (Schlosser, 2006)).

The newest focus of agrifood research addresses the 'Emancipatory Question.' It investigates the relationship between the structure of modern agriculture and the quality of civil rights for all participants. More specifically, it asks what kind of agrifood system might decrease injustice and inequality for farmers/ranchers/growers, farmworkers, food processing workers, and all consumers? How can we transform the agrifood system to be more socially, economically, and environmentally just (Allen, 2005; Hinrichs and Lyson, 2007; Thompson, 2010)? A central dimension of this research has been the discussion of the different position producers experience in commodity versus value chains. Commodity chains tend to be based on indirect sales of undifferentiated global commodities dominated by agribusiness TNCs, whereas value chains tend to be based on value-added dimensions of the chain (such as, organics) and attempts to share the value more equitably. Fair trade (Fair Trade International, 2013; Raynolds *et al.*, 2007) has emerged as an attempt to shift some of the profits along the value chain upstream toward the producers and avoid the power of the agribusiness TNCs that drive the conventional commodity chains. Agriculture of the middle (Lyson *et al.*, 2008) has emerged as an attempt to provide opportunities for those midsized producers who are too large for direct sales but too small to compete in global commodity markets by creating identity-preserved, value-added products. Food policy councils (Winne, 2008) have emerged to bring all stakeholders to the same table in an effort to create and sustain an equitable agrifood system. At the international level, organizations, such as La Via Campesina, are pushing back against the corporate domination of the agrifood system, especially regarding GMO foods, and arguing that food is a sovereign right (La Via Campesina, 2013; Wittman *et al.*, 2010). For many rural sociologists, alternative agriculture movements are viewed as the countervailing force to the corporate domination of the global agrifood system based on neoliberal restructuring that favors market-based governance over democratic institutions (Morgan *et al.*, 2006).

Summary

Rural sociology continues to be a diverse and vibrant field of study. Professional rural sociological associations span the globe. This article provides an overview of rural sociology with particular attention paid to the substantive areas of the sociology of agricultural science and the sociology of agrifood studies (see RSS (2013) for other historical sources). The social, economic, and environmental implications of the globalization of the agrifood system, including the alternative responses to the dominant model, create a rich environment for a long and interesting discourse in the field. A diverse array of social scientists including rural sociologists, agricultural economists, environmental sociologists, cultural geographers, cultural anthropologists, nutritionists, and others bring their particular disciplinary conceptual lenses to bear on the topic. The Four Questions framework (Constance, 2008) – Agrarian, Environmental, Food, and Emancipatory – spans disciplinary boundaries and is useful for organizing the ongoing discourse. Current issues, such as climate change, food sovereignty, land

grabs, governance, and genetically modified food occupy the cutting edge of new discourses. It is noteworthy that DuBois' original concerns regarding sharecropping and contract production are still salient today as agribusiness TNCs, in particular the dominant food retailers, create flexible commodity chains based on global sourcing. Recent research on the quality of life effects of industrial agriculture for rural people provides evidence in support of the critical perspective (Lobao and Stofferahn, 2008). Although the sociology of agrifood studies currently dominates the field of rural sociology, the historical foci of population and community studies, stratification studies, natural resource sociology, ES, and agricultural science studies continue to make theoretical and empirical contributions within those subareas. Similarly, although today the critical perspective enjoys some privilege over positivist approaches, both continue to inform social policy agendas and reflect divergent views of rural society. The issue of GMOs captures this point well. Although advocates invoke an adoption–diffusion perspective that presents GMOs as the answer to world hunger, opponents criticize GMOs as yet another example of industrial domination and marginalization of rural peoples.

Disclaimer

This article is an update of the original article written by Buttel (1994). The early sections of this article follow closely Buttel's original contribution and his later work (Summers and Buttel, 2000), whereas the later sections are informed by recent developments in the field.

S

Safety of Street Food: Indonesia's Experience

A Wirakartakusumah, EH Purnomo, and R Dewanti-Hariyadi, Bogor Agricultural University, West Java, Indonesia

© 2014 Elsevier Inc. All rights reserved.

Safety of Street Food

Statistic of Food Born Incidences in Indonesia

Food safety cases in Indonesia are more likely to be underreported. During 2001–09, for example, it was reported that the number of foodborne disease outbreaks per year was 122, involving 5808 cases and 36 fatalities as calculated from **Table 1** (Suratmono, 2010). Of the 109 outbreaks reported up to November in 2009, 36.7% was associated with microbiological hazards, 20.2% was due to chemical hazards, and approximately 40.4% could not be determined of their causes because of a lack of samples or inconclusive results (Suratmono, 2010). Although data were limited, a higher percentage of outbreaks associated with microbiological hazards have actually been identified in the past few years. However, no particular pathogens have been etiologically linked to most outbreaks.

Outbreaks investigation is carried out by the Indonesia National Agency for Drug and Food Control (NADFC) and Ministry of Health (MoH). In general, limited resources were the reason for limited reported data on the outbreaks; thus, preventive actions could not be established. No particular program has been established to improve the surveillance for foodborne outbreaks or their investigation. However, such programs exist for infectious diseases such as dengue fever, etc. Routine monitoring and inspections of food service establishment with regard to GMP implementation is carried out by NADFC and MoH; however, the coverage is low. A study by Susanti (2010) showed that only 15% of medium/large-scale food industries and 4% of home/small industries throughout the country are inspected routinely. The inspection results during 2005–08 suggested that 85% of the medium/large industry and 60% of small/home industry had implemented GMP satisfactorily

Based on the data that ready-to-eat food served at home or by food service industries were the most commonly cause of outbreaks (**Table 2**), several pathogens, especially those that form spores, could be suspected as the causative agent of the outbreaks. In addition, common practices to store ready-to-eat food at room temperature (danger zone) and large-scale cooking to cater for big parties by food service industries could actually allow some spore-forming bacteria such as *Clostridium perfringens* or *Bacillus cereus* to germinate and cause food poisoning. Another common problem with ready-to-eat food preparation is inadequate sanitation and hygiene implementation, which may introduce nonspore-forming bacterial pathogen such as *Salmonella* to food and cause infection. *Salmonella* is a very likely candidate because it is an important causative agent of foodborne illnesses worldwide. One example was the main cause of food export from Indonesia rejected by the US Food and Drug Administration (2004) and was isolated frequently in various food including shrimp (Dewanti-Hariyadi *et al.*, 2005). The problem with *Salmonella* often results in widespread typhoid fever, considered a major problem in certain areas in Indonesia. In certain endemic areas, a prevalence of 1400 typhoid cases per 100 000 populations has been reported (Suwandono *et al.*, (2005)).

Indonesia's Experience in Street Food Program

Study on street food vendors (data Food Technology Development Centre)

Indonesia has a long experience in improving safety of street food. During the period of 1988–92, the Indonesian Government worked together with the Netherlands' Ministry of Foreign Affairs to establish a program on the improvement of the wholesomeness of common people's food in Indonesia or well known as street food program. The program was designed to improve safety and quality of street food, to improve socioeconomic status of street food vendors, and to formulate policy for the proliferation of the program. The first phase of the program was basically a base line survey to map initial situation of the socioeconomic status of street food vendors, the quality and safety of street food, and street food handling.

In the early 1990s, the income per capita of those who are working on street food business is more than double of the minimum wages apart from the fact that they had rather limited educational background (67% of street food vendors had elementary school education or less). At the same time, street food business was able to provide jobs for 12.2% of workforce. Interestingly, 30% of food spending of household was for street food. Such a situation illustrates the importance of street food business and its impact on the community. Street food has significant roles in providing nutrition, to some extent, for the community. However, classical problems on safety of street food were also identified. The major food safety concerns are microbiological and chemical contamination. Poor food handling was also one of the major findings.

Table 1 Foodborne disease outbreaks in Indonesia during 2001–09

The results obtained from the first phase were used to design the intervention programs which include general intervention, intervention on special product, pilot project, and mass media campaign. Intervention was done through involvement of the local government to ensure the smooth transfer of the idea and sustainability of the program. Task force for the intervention program consists of not only experts from universities but also local government officers, directly responsible to manage street food, and informal leaders in the community.

Study on school children's meals intake

In most cases, meals intake of school children in Indonesia is obtained from school canteen and/or street food vendors in the premises or immediate area of the school. Only a small fraction of school children bring their own meal from home. Therefore, the efforts to improve the safety and quality of food provided by school canteens are highly justified.

Even though the Republic of Indonesia Government regulation no. 19/2005 requires school to have at least one canteen, 40% of elementary schools have no school canteen. Unfortunately, 84.3% of the school canteens in elementary schools are below the minimum standard for sanitation and personal hygiene. Lack of proper school canteen forces school children to buy their school meals from street food vendors around the school, which are beyond the control of the school. In general, employees of school canteen and street food vendors have very limited knowledge of food safety and personal hygiene.

A report of NADFC indicated that in average approximately 38% of food sold in school canteen is potentially unsafe (NADFC, 2006). Percentage of potentially unsafe food for different food categories is presented in Table 3. The food is potentially unsafe because it may contain nonfood grade chemicals, contain food additive above its permitted level, may be contaminated by pathogen microbes, or may have extremely high microbial load. In addition, most of the foods sold in school canteens are snack foods and soft drinks which may result in imbalance of nutritional intake and or unhealthy diet.

This condition drove the ministry of education and culture of the Republic of Indonesia to launch Healthy Canteen program in 2009. The program was aimed to improve the facilities of the school canteen as well as improve the food safety there. Two main activities in the program were improvement of canteen facilities and capacity building. The program covered 288 school canteens in 2009 and it continued till 2011.

Remaining Challenges for Food Safety

Misuse of food additives

Food additives such as colorant, sweetener, and flavor enhancer are often misused in street food. They are frequently used in excessive amount, resulting in concentration above its maximum level. Street food vendors do not pay much attention to the label and instruction to use the additive. Another type of food additive misuse is its use not in accordance to its intended function. Classic example is the use of one of the famous flavor enhancer (monosodium glutamate) to provide salty taste instead of its intended *umami* flavor. As a result, they tend to use excessive amount of monosodium glutamate as it has to serve a different function.

Abuse of nonfood grade chemicals

A more classical problem of food safety in Indonesia is the abuse of certain nonfood grade chemicals in food processing. Formalin, a formaldehyde-containing solution, is often used to preserve fish, tofu, and wet noodles. Publication of the findings in 2006 had also caused a loss of some domestic trade, especially for the three aforementioned commodities. There were several reasons why the problem occurred. First, it was easy to access and obtain the chemical which was supposedly used for glue making and corpse preservation. Secondly, inadequate sanitation during production and lack of cold chain or refrigeration system has resulted in a short shelf life. The condition has prompted certain individuals to apply formalin to lengthen the shelf life without considering the risk of the hazard to human. The first problem was solved by a collaborative effort between NADFC and Ministry of Industry and Trade in a better management for the trade of hazardous chemicals. The second is handled through continuous education in food hygiene and sanitation process. Because refrigeration or cold chain has not been addressed adequately, the formalin problem has not been fully managed. The government routinely inspect presence of this chemical in foods, especially those that have previously been linked to the use of formalin. Sanctions for the abuse of hazardous chemicals use in food have actually been regulated in Law no. 7, 1996. The above incident has increased the law enforcement for such abuse.

Intervention to Improve Safety

Establishment of Street Food Pilot Project

Street food pilot project was first introduced in the city of Bogor under the street food program. The pilot project was designed as part of the street food program which was a collaborative program between the Government of Indonesia and the Government of Netherlands (Winarno, 1993). Street food pilot project was started in 1990. During the first year of the pilot project of the intervention (1990–91), all the activities were organized and executed without involvement of the local government. In the second year of the intervention, the local government was invited to actively be involved in the pilot project to secure the sustainability of the program. The active involvement of local government is realized in the formation of task forces involving government officer down to the village (*kelurahan*) level. The task force functions as facilitator as well as assessor. The local government contribution to the pilot project was also indicated by legalizing the activity of street food vendors in the pilot project zone. Before the pilot project, street food vendors were considered illegal and therefore would create insecurity for the vendors.

School Canteen Intervention

Selection of scope of study/target group

School canteen provides food for school children who are one of the most vulnerable groups of consumers. School canteens to receive intervention package were selected on the basis of several minimum requirements. A school must already have canteen with continuous and reliable supply of clean water. It is impossible to have a school canteen that is able to produce safe food without proper supply of clean water. Candidates for school canteens program were proposed by local government. A team from the ministry of national education directly inspects the proposed canteens to assess the suitability of the school canteens for the program. The canteen personnel, teachers, and school principals were invited to join capacity-building program as well as planning for facility improvement of the school canteen.

Capacity building

For school canteen management and employees

Healthy school canteen program targets to improve canteen facilities by providing significant amount of money. However, it is fully realized that the canteen facility improvement alone will not make significant difference without capacity building of those who are working daily in the canteen. Therefore, facility improvement and capacity building are given as one package to the target school.

Capacity building is given in the form of trainings on nutritionally balanced and healthy diet, food safety, good manufacturing and handling practices, and food sanitation and personal hygiene. The teaching materials are simplified to suit the need of school canteen employees. To ensure that the school canteen optimally use the money to improve the facilities, the trainer and the trainees discuss their plan in class. Such an approach stimulates fruitful discussion among trainees to optimally improve the canteen facilities within the provided budget. The discussion is also very useful for school canteen personnel to further improve the facilities in the future by developing list of priority for next facilities improvements.

For teachers and school principals

Capacity building of school canteen program targeted not only canteen personnel directly related to canteen operation but also teachers and school principals. The idea is to ensure that school canteen program is properly understood and fully supported by teachers and school principals. Capacity building of teachers and school principals is strategically important because of the authority that they have over the school canteens. Teachers are supplied with all the teaching materials used during the training. They are requested to share their knowledge with their students in order to create awareness among school children and to create high demand for safe food. The success of creating demand for safe and healthy food is highly dependent on the willingness of the teachers.

School principals are actively involved in the discussion of improvement of school facilities. It is important that they have field experience of implementing the knowledge obtained in the training class to practically solve their unique problem in their school.

Early food safety education to school children

School canteen program facilitates the improvement of school canteen in elementary school, junior high school, and senior high school. In 2009 alone, 288 schools which consist of 111 canteens in elementary school, 91 canteens in junior high school, and 80 canteens in senior high schools were involved in the program. School canteens are targeted because they cater food for the young generation as part of early food safety

Figure 1 Street food at Bina Marga Street, City of Bogor, Indonesia. Reproduced from Kementerian Koperasi dan, U.K.M., 2012. Final Report on Street Food Pilot Project (in Bahasa Indonesia).

education. This figure indicates that slightly higher proportion of canteen in elementary school is targeted in the program. The safety of street food from school canteens improved in 2012, the NADFC reported that the percentage of potentially unsafe food sold in school canteen decreased to only 23.1%.

Integrated Intervention of Street Food

Street foods are mostly provided by informal sector. Street food vendors often use public area and public facilities for their activities and consequently create social problems. However, informal sectors have also shown its significant contribution in providing jobs and economy. The incomes of those who are working in this informal sector are higher than regional minimum wage (UMR). Therefore, an integrated approach is required to minimize the negative social effect of street food, improve the safety and quality of street food, and maximize the economic contribution of street food.

Integrated intervention of street food includes activities to improve food safety, legal aspect of street food activities, financial support, and social engineering. The integrated approach was started in 2009 by ministry of cooperative and small and medium enterprises in collaboration with Bogor Agricultural University as a study to develop integrated model of street food vendors. The pilot project of intervention program started in 2011 and will continue till 2013 in Bogor. The integrated intervention program involves local governments, universities, nongovernment organizations, NADFC, and ministry of social affairs.

The first step in the integrated program is to legalize the activity of street food vendors through the establishment of 11 zones of street food vendors in Bogor. This was done through establishment of a decree by the city mayor. Four out of 11 zones are selected as pilot project for the integrated intervention. The selection was based on the number of vendors per zone, priority of local government, and availability of basic infrastructure such as water supply and electricity. Street food vendors are facilitated to form two cooperatives, namely cooperative *Selobang* and cooperative *Bhineka*. Capacity building on food safety includes several topics such as food additives (preservative, sweeteners, and colorant), food packaging, basic sanitation, and hygiene, which are all provided to street food vendors. Moreover, they are trained for simple accounting and business management. Financial support is given in the form of collective loan. The collective loan is aimed to form unity among cooperative members. Street food vendors are also facilitated to have business meetings with potential funding source such as banks and microfinance agencies. Local Government (City of Bogor) is fully supportive in rearranging and controlling the traffic in the intervention zone to minimize traffic jam and reducing air pollution/improving air quality. Cooperative office of the city is directly involved in the establishment of the cooperatives as well as mentoring and monitoring the activities of the cooperatives.

Evaluation of the program shows that business performance of street food vendor increases as indicated by the rise in total revenue (14–16%) and improvement in income (9–12%). (Kementerian Koperasi, 2012). The facilities and infrastructure of street food vendors in the intervention zone is significantly improved as shown in Figure 1. The improvement includes trash bins, sewage system, toilet, hand-washing facilities, cleaning area, and parking lot.

Lessons Learned

Long experience of Indonesia in improving safety of street food indicates that safety aspect of food is not independent of

other factors. Relatively low concern of food street vendors is mainly due to their lack of food safety knowledge and the absence for demand on safe and wholesome food from consumers. Therefore, efforts to improve safety of street food must come from both consumers and producers. Food safety education from the very early childhood is required to internalize food safety concept to the children.

Street food vendors have significant contribution to the local economy and are actually able to provide safe and good-quality food. However, they need capacity building in basic knowledge of food safety and business management. Intervention and facilitation from the Government are often required to link these microenterprises to commercial funding scheme in order to help them develop their business.

Glossary

Check-all-that-apply (CATA) A type of question, frequently used in survey questionnaires, that presents subjects with multiple response options to a single question. Participants are instructed to select as many of the response options that they perceive to be relevant. The list of answer options is not limited to product attributes and can relate to product usage, concept fit, or hedonic or emotional aspects.

Descriptive profiling/analysis Techniques that aim to generate quantitative data describing similarities and differences within a product set. While each approach is slightly different, the basic methodology is the same. The steps of descriptive analysis are selection of panel members, term generation, concept formation, testing of panel agreement, and finally, evaluation of products. Some of the techniques available include free choice profiling, the spectrum™ method, Quantitative Descriptive Analysis™, Flavor Profile method, texture profile method, Flash Profiling, and generic descriptive analysis.

Direct scaling A technique for estimating perceptual intensity proposed by S.S. Stevens that assumes individuals can directly generate a psychophysical function. Common direct scaling methods include magnitude estimation and the Labeled Magnitude Scale, and the general Labeled Magnitude Scale. This contrasts indirect methods based on signal detection theory.

Just Noticeable Difference (JND) A mathematical relationship defined as the smallest detectable difference between two levels of a sensory stimulus. Originally described by Ernst Weber and Gustav Fechner.

Method of limits One of the three traditional methods for testing subjects' perception, the other two are the method of constant stimulus, and the method of adjustment. The method of limits is a technique to determine thresholds, usually detection threshold. The technique can be performed as an ascending or descending method of limits. In the ascending method of limits there is some property of the stimulus (e.g., sweetness) that starts out at a level low enough that the property cannot be detected. The level of this attribute is slowly increased until the participant indicates that they can detect the attribute in the stimulus. The descending method of limits is conducted in the opposite order, decreasing until the participant indicates that they can no longer perceive the specific attribute.

Perceptual mapping A collection of techniques that can produce visual representations of perceived product relationships. These techniques, including pairwise comparisons, sorting, and mapping, are popular tools in market research as they can be used to evaluate product space within the market. Using these techniques, large datasets can be reduced to easily interpreted plots of a few dimensions. While it is not necessary to the techniques, these maps often also contain relevant product attributes, which lend interpretability to the map. Depending on type of data collection methods used, data from DA can be analyzed with principal component analysis, multidimensional scaling, multi-factor analysis, General Procrustes Analysis, and discriminant analysis.

Psychophysics A subdiscipline of psychology that qualitatively measures the relationship between physical stimuli and the sensations and perceptions evoked by these stimuli. The term 'psychophysics' encompasses the study of the stimulus-response relationships as well as the methods used for these studies.

Sensory evaluation An applied science focused on the study of product characteristics as they are perceived by human assessors via the senses.

Sensory science A discipline encompassing of fields of sensory evaluation, psychophysics, sensory and affective neuroscience, chemosensory biology, and genetics. The primary distinction between sensory evaluation and sensory science is that the former focuses primarily on methods used to study product characteristics while the latter includes study of the participant in addition to the product.

Signal Detection Theory (SDT) Used to measure decisions made under conditions of uncertainty. Signal detection theory assumes that any stimulus consists of a signal (audio tone) and noise (white noise). Using SDT based methods researchers can separate an individual's sensitivity from their response bias.

The general Labeled Magnitude Scale This scaling technique uses a line marked with empirically derived verbal anchors describing different sensation intensities (e.g., 'weak,' 'moderate,' 'strong'). This scale was developed as a way to evaluate perceptual differences in sensation intensity between participants, to avoid the rescaling problem in magnitude estimation.

Visual analog scale (VAS) A type of scale used frequently used to measure characteristics or attitudes that cannot be directly measured, such as how much someone likes/dislikes a product. When using the scale, panelists indicate their level of agreement to a statement by marking a point along a continuous line, somewhere between the two end points (e.g., 'strongest liking of any kind' and 'strongest disliking of any kind'). This scale is differentiated by discrete scales, such as a Likert scale, because of its continuous nature. This feature allows for a wider range of statistical techniques to be applied to data generated by a VAS though generally the sensitivity and reliability of the two types of scales (continuous vs. discrete) are very similar.

 doi:10.1016/B978-0-444-52512-3.00065-6

Introduction

Sensory evaluation is defined by the US Institute of Food Technologists (IFT) as the "scientific discipline used to evoke, measure, analyze and interpret those reactions to those characteristics of foods and materials as they are perceived by the senses of sight, smell, touch, taste and hearing" (Stone and Siedel, 1985). As with any other scientific discipline, the keywords here are measure, analyze, and interpret. The traditional focus of sensory professionals has been the development of tools to make accurate, reproducible measurements with regard to food products. Originally, many of these approaches were empirical and atheoretical; sensory practitioners used what worked, and these approaches were codified into putative best practices. However, because the instruments used to make sensory measurements – human assessors – are inherently noisy, it can be difficult at times to separate the signal from the noise. Thus, a second major area of research has been the development of the experimental methods and statistical models needed to quantify and test human sensory data. In a similar vein, the modern sensory professional needs to be well versed in aspects of psychology and cognitive science in order to understand and ideally reduce potential biases when collecting data from human participants. At multiple points throughout the history of the field, the state of the science has been enhanced by fruitful collaborations and cross talk between applied sensory practitioners trained in food science, academic psychophysicists, and behavioral scientists trained in experimental and cognitive psychology.

The authors have intentionally chosen to title this article sensory science rather than sensory evaluation or sensory analysis, because they believe that the field of sensory evaluation is only one facet within a broader field of sensory science (i.e., the two disciplines are not entirely synonymous) and that the former is a subset of the latter. Sensory evaluation has classically focused on the product (as evidenced by the IFT definition above), whereas the broader field of sensory science also includes study of the person in their own right and how this influences their responses to products, that is, sensory science includes not only sensory evaluation but also psychophysics, sensory neuroscience, affective neuroscience, chemosensory biology, and genetics (Figure 1). Related but separate fields include ingestive behavior and flavor chemistry. As appropriate, aspects of some of these disciplines will be included in this article to provide insight into the sciences that underlie the applied aspects of sensory science.

Convergence of Sensory Evaluation and Experimental Psychology

Rose Marie Pangborn is generally acknowledged as the matriarch of a scientific sensory analysis in the US. During her tenure at the University of California, Davis, CA, USA, she published more than 180 scientific papers, mentored more than 40 graduate students, and coauthored one of the historic textbooks in the field (Amerine *et al.*, 1965). She cofounded the Association for Chemoreception Sciences and today, the biennial Pangborn Sensory Science Symposium, the premier international conference on applied sensory science, and an international scholarship for the doctoral training of academic sensory scientists bear her name. Many of today's senior sensory academics and practitioners internationally received their initial training under Prof. Pangborn.

Near the end of her career, Pangborn was asked why the literature on taste interactions in actual foods and beverages was so sparse and unsophisticated. In her reply, she made a sharp distinction between sensory analysts (trained in food science) and psychophysicists (trained in experimental psychology; Pangborn, 1987). Specifically, Pangborn called for more collaboration between food scientists and psychophysicists, noting that it was "unusual for sensory analysts to use

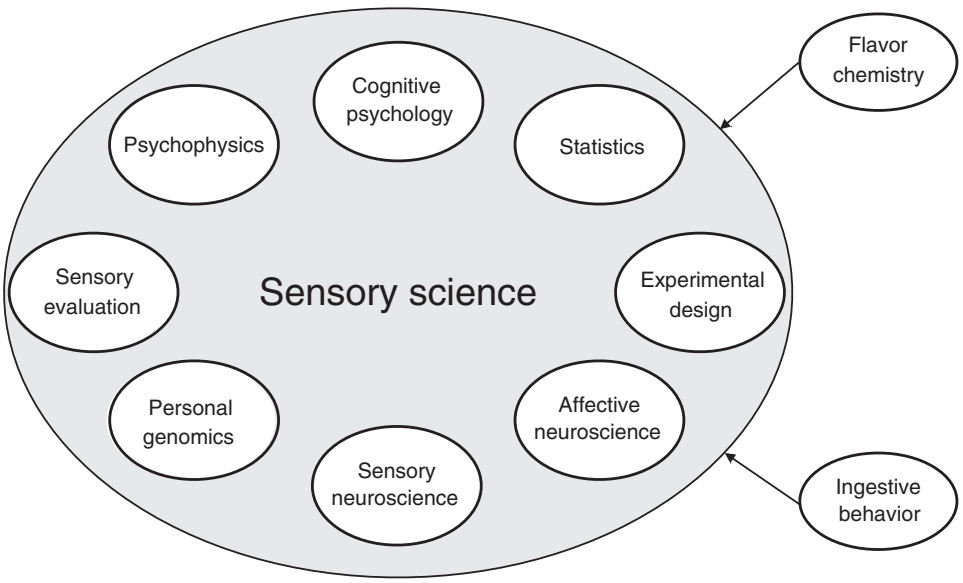

Figure 1 Schematic of contributing disciplines to sensory science.

good psychophysics and for psychophysicists to be well informed about the multiple functional properties of foods." Later, Lawless (1991) similarly lamented the substantial disconnect between basic research conducted by academic researchers and industrial practice.

It is no longer the case that psychophysics and sensory analysis are disconnected. For example, the authors of this article include an experimental psychologist formerly employed in both university food science and psychology departments and a food scientist trained in psychophysics and sensory neurobiology. Also, a key textbook on sensory evaluation in use today is coauthored by a wine scientist and a psychophysicist (Lawless and Heymann, 2010). Many active researchers in the field have strong training in both food science and psychology. Accordingly, it is not uncommon for articles in the modern sensory science literature to use strong psychophysics while drawing on methods from a variety of food science disciplines (e.g., Bakke and Vickers, 2008; Harwood *et al.*, 2012; Lucas *et al.*, 2011).

Much of the early cross-fertilization between sensory analysis and experimental psychology can be traced to the Behavioral Sciences Division at the US Army's Natick Laboratories under the leadership of Dr. Harry L. Jacobs (Meiselman and Schutz, 2003; Moskowitz, 2004). These laboratories have produced many of today's leading scientists in both basic and applied sensory research. As noted by Moskowitz (2003b), the normal pattern of practice following foundational science was reversed for sensory science, with practice coming well ahead of its theoretical framework. The pioneering work of the psychophysicists at Natick helped provide both a corpus of basic knowledge and academic credibility that moved sensory specialists beyond their traditional service function as 'taste testers' (Moskowitz and Gacula, 2003).

Notably, the cross-fertilization between psychology and food science was bidirectional. Psychologists like S.S. Stevens claimed that participants could only rate a single attribute in a session (Moskowitz *et al.*, 2003) when applied practitioners were regularly collecting such data during the course of descriptive profiling (Stone *et al.*, 1974). Only later did psychophysicists abandon the uniattribute rating paradigm (Moskowitz *et al.*, 2003) once it was shown that individuals could rate multiple attributes (Bartoshuk, 1975).

Collectively, bidirectional collaborations and cross-disciplinary conferences helped to infuse applied sensory practice with a theoretical foundation, both by influencing the training of future generations of sensory scientists and via collaboration among established researchers with domain expertise in different fields. A recent example of this collaborative approach is the application of modern psychophysical scaling methods, together with flavor chemistry and plant genetics to optimize tomato flavor (Tieman *et al.*, 2012). For additional discussions of how psychophysical thinking has helped to move sensory analysis from a set of measurement tools toward a mature discipline of study, the interested reader is referred to several reviews (Meiselman and Schutz, 2003; Moskowitz, 1993, 2003a).

Once the field was based on a theoretical foundation rather than revealed wisdom, it became possible for the sensory professional to move beyond simple dogma and 'break the rules' when appropriate, for example, asking naive, untrained panelists to rate intensity, not just liking (Moskowitz *et al.*, 2003). Nonetheless, even when working within a broader theoretical framework, 'the demand for practical testing is so great that the pursuit of causal mechanisms and general principles may be lost in the daily rush to solve immediate product development' (Cardello, 2005).

Distinctions between Sensory Science and Commodity Judging

Applications of sensory science represent a different historical and philosophical tradition from commodity judging. In commodity judging, the emphasis is placed on identification of standard defects by highly trained expert judges. Examples of this approach include coffee cupping (e.g., Specialty Coffee Association of America Q-grading), wine scoring (e.g., the University of California, Davis, CA, USA, 20-point scoring system), and dairy products judging (Clark and Costello, 2009). These approaches are fast and work reasonably well for narrowly defined systems with known defects – that is, in quality control settings. However, the necessary expertise and relevant attributes do not generalize outside the specific context of the individual commodity: a coffee Q-grader cannot be used to judge wine, and standard ballot items appropriate for pasteurized cow's milk may not apply to goat's milk.

Commodity judging has been criticized on the grounds that it focuses on causes rather than perceptions (e.g., 'light-struck' flavor), generates numbers that are not suitable for statistical analyses (ordinal vs. interval measurements; see Section Scaling), and lacks an underlying psychophysical model ('scoring is not scaling'). Additionally, it is important to remember that expert opinions may differ from those of consumers. For example, cork taint is a severe defect according to wine experts, but consumer testing indicates that the presence of low but detectable amounts of trichloroanisole (TCA) may not depress consumer acceptability (Prescott *et al.*, 2005). Finally, commodity judging assumes a singular purpose or appropriateness that does not match the multitude of ways packaged consumer goods are used (e.g., a can of mushroom soup can be used in a casserole or eaten as soup and may simultaneously be acceptable for one use but not the other).

Sensory Measurement

Classical Psychophysics

The origins of experimental psychology lie in efforts to understand the ways in which the information present in the world in the form of energy came to be translated into one's perceptions (the recommended reference for this section and the section to follow is Gescheider (1997)). Gustav Fechner, in his Elemente der Psychophysik (1860), approached this question by reducing the problem to meaningful and perceptually equivalent chunks known as just noticeable differences (JNDs). His measurements indicated that as stimulus energy (photons, sound pressure level, etc.) increased, a greater amount of this energy was required to produce a JND. Fechner

described the relationship between stimulus energy and perception mathematically, producing the first psychophysical function relating external stimuli and internal perceptions. He also attempted to operationalize the scaling of stimulus magnitude by promoting the idea of counting JNDs above threshold. Because JNDs are perceptually equal, any stimulus magnitude should be quantifiable as the sum of JNDs, producing in effect a type of magnitude scale.

The idea of JNDs was incorporated into attempts to measure discriminability between different stimuli. Ernst Weber, investigating the thresholds for perception of different weights, formulated what is known as Weber's Law (or Ratio). The law states that for a given sensory modality (salt taste, sound, weight, vibration, and so on), the change in intensity needed to produce a perceptible change (a JND) in sensation intensity is a constant fraction of the initial stimulus intensity. Hence, the absolute value of the JND may vary, but its value as a proportion of the stimulus energy does not. For example, the Weber ratio for saltiness has been estimated at 0.08, indicating that a minimum 8% increase in salt concentration (at least in water) will be apparent irrespective of the current salt concentration that is being increased.

These ideas have formed the basis for what is known as classical psychophysics and hence the basis of measurement of perception, whether in psychology or sensory science. From the concept of psychophysical functions comes the understanding of the relationship between a physical stimulus and the sensations evoked by that stimulus. In food sensory science this might be, for example, amount of salt and the impact of increasing the salt level on perceptions of saltiness. Ultimately, of course, determining such relationships helps one to understand consumer responses to salt (e.g., Hayes *et al.*, 2010). Psychophysical functions are almost always above or below unity – in other words, there is not a one-to-one linear relationship between stimulus magnitude and perceptual intensity. For instance, adding 20% more sucrose to a drink will not make it 20% sweeter.

Fechner described psychophysical functions as following a log relationship, but more recent research by Harvard psychologist S.S. Stevens has shown that the function is better fit by an exponent in an equation known as Steven's Power Law. This has provided a convenient way of describing psychophysical functions: so, the exponent for sweetness is 1.3, whereas that of coffee odor is 0.55. In effect, for every unit of increase of sucrose concentration, the intensity of sweetness is increased by 1.3 (log) units; conversely, a unit increase in coffee odorants leads to an increase of only 0.55 in coffee odor intensity.

The input of classical psychophysics into food sensory science has been invaluable in answering questions related to the perception of ingredients within foods as well as the effects of manufacturing processes, packaging, and storage. It is crucial, for example, to determine thresholds for ingredients that may have functional properties but which may adversely affect consumer preferences. Similarly, knowing whether an ingredient can be reduced or substituted, or a process changed will rely on determination of absolute threshold (that is, above some point below which a quality cannot be detected) or difference/discrimination thresholds, which are related to change. Answering these applied questions requires the estimation of JNDs at different points on the stimulus continuum.

In classical psychophysics, there are several approaches to determining absolute thresholds. The method of limits involves presenting a series of stimuli above and below the estimated threshold, in either (or both) ascending or descending series. Each 'yes' response (the stimulus is present) terminates the series and the threshold is taken as the average value over several such series either for an individual or across a group of individuals. In the staircase method, a series of stimuli ascends from below threshold until the stimulus is detected, and then reverses direction, descending until the stimulus is not detected. The threshold is the average of several (4–7) 'reversals.' The method of constant stimuli uses a set of 5–9 different values, from never detected to always detected, presented randomly, and the percentage of detections as function of stimulus intensity is determined. Here, threshold is the stimulus intensity for which the proportion of 'yes' responses is 50%.

Difference thresholds can be determined using similar methods except that on each trial there is a comparison between a reference sample and a different (more/less intense) sample. As an example, to a question such as "What change can I make in the sucrose content of an orange drink (10% sucrose) without a noticeable difference (JND)?" the stimuli might range from definitely less sweet (e.g., 3% sucrose) to definitely more sweet (e.g., 18% sucrose). In this version of the method of constant stimuli, a series of eight values between these two extremes would constitute the comparison stimuli. At each concentration of comparison stimulus, the panelist would be presented with a pair of stimuli (the reference stimulus plus one of the comparison stimuli) and asked to indicate which is the sweeter: the reference or the comparison? Clearly, if only 50% of the responses are that one stimulus is sweeter, it means that there is no discrimination from the reference. Similarly, 100% and 0% 'sweeter' mean perfect discrimination. Conventionally, the point at which discrimination occurs – the difference threshold – is taken as 25% (reference sweeter) and 75% (comparison sweeter), which is 50% of responses, adjusted for guessing.

This type of paired comparison test is in common usage for determining simple differences between samples (ISO5495, 2005). In this case, panelists are given two samples and asked to pick the one with the greater intensity. For example, given two sucrose solutions differing in concentration, a panelist would be asked to 'select the sweeter of the two.' The probability of guessing correctly by chance alone is 0.5, so a judgment on whether the samples are different relies on repeated trials with the same person or, more typically, across multiple panelists. Tables of binomial probabilities will indicate, for instance, that 21 out of 30 panelists correctly picking Sample A as the sweetest (when it has the higher concentration of sucrose) is significant at $p < .05$. The paired comparison test is an example of a directional test in which the quality of interest (in this case, sweetness) is specified.

A group of tests known as alternative forced choice (AFC) tests function is exactly the same way but are used with three (3-AFC) or more (n-AFC) samples (ISO13301, 2002). Hence, a panelist might be told that of the three sucrose solutions in

front of them "two are of the same sweetness, one is sweeter – pick the sweeter sample."

Nondirectional tests, which are generally less sensitive than directional tests (for a theoretical explanation of this, O'Mahony *et al.*, 1994), ask the panelist only to identify differences between samples, irrespective of quality. So, the duo–trio test (ISO10399, 2004) asks panelists to match one of the two unknown stimuli to a reference ("indicate which sample is the same as the reference"). The 'ABX' test is simply an inverted duo–trio, with two references and one unknown: panelists are asked to match the unknown (X) to reference A or B. The very commonly used triangle test requires a slightly different cognitive strategy: panelists are told that of three samples, "two are the same, one is different – pick the odd sample" (ISO4120, 2004). As with the paired comparison test, determining whether or not to accept a difference is based on binomial probability tables in relation to the guess rate (e.g., 0.33 for three samples). The cutoff for significance is not a fixed proportion because the confidence interval shrinks as the number of panelists increases: for example, with 60 panelists, 33 or more correct identifications (55% correct) are required for statistical significance, whereas only 58 correct identifications are required with 120 panelists (48%).

Most recently, there has been an increasing interest in the tetrad test, in which four samples are sorted in two groups of two, based on a perceived difference (Ennis and Jesionka, 2011). As noted above, there are differences in the sensitivity of discrimination tests such that the power of the tests to detect differences for a given number of panelists can be estimated. When this is done, the tetrad test can be shown to be far more sensitive than, for example, the triangle test. In practice, this means that far fewer panelists need to be used in this test in order to obtain the same likelihood of detecting a real difference.

Failure to find differences in a detection or discrimination test cannot, of course, be used as evidence that there is actually no difference between samples, as this will depend on the power of the test and the number of participants. There is always some risk of a failure to find a difference that is actually present (a Type-II error). However, in some applications, for example, product claim substantiation, there is a need to make statements about equivalence, and hence there have been developments in methods for such applications (Ennis and Ennis, 2010).

The A–Not-A test, in which the panelist indicates whether a sample is identical to a reference sample ("Is this sample the same as A (the reference) or not?") has also been commonly used (ISO8588, 1987). There is a crucial difference, however, between this test and those mentioned above. In the paired comparison, *n*-AFC, triangle, and tetrad tests, the panelist is told both that there are differences present among the samples and where more than two samples are judged, how many are the same and how many are different. By contrast, the A–not-A test introduces uncertainty about the presence of differences between the samples. The so-called forced choice tests, such as the triangle test, provide information that eliminates uncertainty about differences being present and in effect forces one to choose which sample is different/stronger. The importance of this distinction is covered in the Section Signal Detection Theory.

Signal Detection Theory

Because panelists may differ in how strict or lax they are in deciding whether a stimulus is present or that two stimuli are different, this may introduce a bias in estimating thresholds. This can be understood most easily by considering what is being measured when it is asked about differences or a threshold is tried to be determined. Thresholds are defined in terms of the stimulus – for example, a threshold of 0.01 M NaCl in water – but are based (as noted above) on the proportion of responses reporting presence of, or change in, the stimulus. The key question thus becomes one of how an individual makes a decision regarding the presence or absence of a stimulus (detection) or the occurrence of one type of event over another (discrimination). Green and Swets (1966) proposed that such decisions can best be understood by treating detection as a process determined by a combination of sensitivity to the signal and the tendency of the observer to report the presence of that signal. In their signal detection theory (SDT), they noted that a tendency to report the presence of a 'signal' could be influenced by external factors. These include such things as considering the implications ('payoffs') of reporting or not reporting a signal. As an obvious example, a simple desire to be seen as sensitive in the task being performed could bias a panelist in favor of reporting 'yes' on every trial in which a stimulus could be present in a threshold task. Thus, how often a person says 'yes' to a stimulus must be judged relative to how often they tend to say 'yes' on any trial, including trials on which the signal is absent (called noise trials), that is, the proportion correct must take into account the prevalence of 'false alarms (FA).'

As all detection or discrimination tasks take place in a context in which the presence of a stimulus or a stimulus difference is not obvious – that is, when uncertainty is present – the panelist is relying on how confident they are that a signal has occurred. At this point, even personality traits can be influential, that is, is the panelist a 'risk taker' or perhaps more judicious? If, in addition, there are financial or other consequences, a bias to respond can be present. In a case in which a panelist has to decide whether or not a taint has affected a batch of ice-cream, the decision takes place against a background of deciding what is worse: responding that 'yes' the taint is present and dumping the production run or deciding 'no' and possibly incurring the wrath of consumers. Being unclear about whether the taint is present allows both 'FA' and 'misses' (in addition to 'hits' and 'correct rejections (CR)'), and an imbalance in the consequences may push the decision toward one or the other.

Underpinning SDT is the realization that sensitivity to a stimulus or stimulus difference is not simply a case of 'stimulus absent' at a given stimulus magnitude and 'stimulus present' at some higher magnitude. For Fechner, a threshold stimulus was one that 'lifted the sensation or sensory difference over the threshold of consciousness,' implying a sharp boundary (a step function) between not detectable and detectable. In fact, data collected during threshold or difference tasks form a flattened S-shape curve (known as an ogive). This suggests that signals emerge into awareness gradually, reflecting points on the stimulus continuum during which the panelist is uncertain whether or not the signal has occurred.

One of the major theoretical contributions of SDT was to adopt the idea of signals and noise that were used in engineering contexts. In SDT, all threshold perceptual events consist of signal embedded in noise. The analogy is that of a weak radio signal that is heard against a background hiss or crackle and is hence unclear. In SDT, noise is always present – it can be neural or environmental, including actual noise, unwanted odors, a background or residual taste or flavor, or distracting thoughts. Hence, decisions about whether or not a signal is present are always about detecting the signal in the noise.

The major practical contribution of SDT to sensory science is that the panelist can be presented with simple task: Does this solution contain a salty taste or not? or Which of these two solutions contain the salty taste? As noted above, this allows uncertainty because a signal (saltiness) may or may not be present. This is dealt with in SDT by representing all responses as either noise trials (N; no signal present) or signal+noise trials (S+N; signal present). Both sorts of event over many signal values are represented as normal distributions of responses that overlap (**Figure 2**): the greater the overlap, the harder it is to distinguish S+N from N alone. In other words, it is difficult to detect the presence of the stimulus or stimulus difference. With these two distributions, all responses can be divided into hits (S present – 'yes'), misses (S present – 'no'), FA (S absent – 'yes'), and CR (S absent – 'no'). Critically, this allows the experimenter to separate response bias (lax or strict criterion for indicating a signal) from the unbiased sensitivity for a modality by comparing the correct 'yes' responses (hits) with the tendency to say 'yes' (hits+FA).

This comparison leads to a simple measure of sensitivity known as d' (d-prime), the difference between the means of the S+N and N distributions in standard deviation units. The values of d' range from 0 (complete overlap; signal impossible to detect) to >3 (effectively no overlap; signal easy to detect). Using d' provides an advantage over forced choice tests based on the binomial distribution in that the degree of discriminability is no longer based on proportions of responses, but rather can be given as a numeric value that is constant irrespective of sample size.

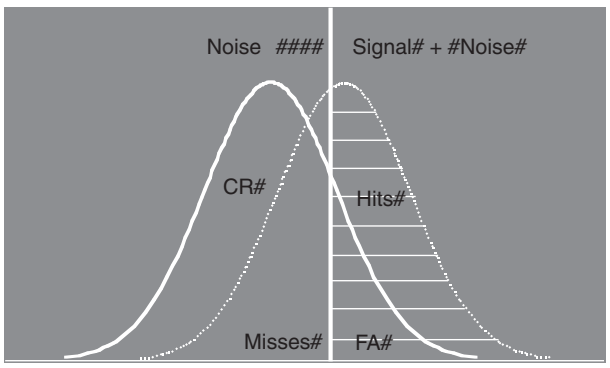

Figure 2 Schematic of overlapping distributions of noise and signal +noise. The difference between the means of these distributions is d', which will increase as the distributions separate, reflecting increased signal discriminability. Overlaid on these distributions are the areas under the curves that represent the proportion of hits, FA, CR for a given criterion, β (shown as the upright). Note that moving the criterion to the left (more liberal in saying 'yes,' a signal is present) or right (more conservative) will alter the relative proportions of these responses types but have no effect on the separation of the distributions themselves. Hits (S present – 'yes'); misses (S present – 'no'); FA (S absent – 'yes'); CR (S absent – 'no').

Of lesser interest in most cases is the fact that SDT approaches also provide a measure of response bias (β) that is independent of sensitivity. This is based on measures of where the panelist places their criterion. Panelists wishing to be seen as maximally sensitive, for example, will respond 'yes' with a lax criterion so that there will be few misses, but at the cost of increasing the number of FA. Alternatively, adopting a stricter or more conservative criterion ("I really want to be sure that the signal is present before I say 'yes'") means that there are few FA, but proportionally more misses. Note that these decisions occur against background of a constant degree of overlap of the distributions and hence a constant sensitivity.

Although SDT provides a strong theoretical framework for understanding of detection and discrimination processes, many sensory practitioners still rely on binomial tables to interpret forced choice results, rather than measuring directly. This is partly due to the need to run large numbers of trials to get stable and accurate estimates of d' and β and partly a result of the lack of training in theoretical psychophysics traditionally received by food scientists. Nevertheless, understanding the basis of SDT is crucial to understanding how humans behave when making decisions. This is reflected in some recent attempts to promote the conversion of proportions of discriminators, as the measure in routine discriminations tests into measures of discriminability such as d' (Jesionka *et al.*, 2014).

Scaling

As discussed in Section Classical Psychophysics, classical psychophysics was also initially concerned with questions of how to measure magnitude. Fechner's solution of measuring JNDs over a wide stimulus range is largely impractical because of the effort involved. Instead, the main approach has been to search for methods of direct scaling. At first glance, scaling seems to be deceptively simple and one is frequently asked to provide a number between 1 and 10 to describe an experience (How painful? and How much effort?). But, a deeper understanding of how numbers are used in scaling becomes crucial depending on the types of information that one is seeking.

The simplest form of measurement is ordinal and is reflected in the straightforward procedure of ranking two or more samples in order of intensity (ISO8587, 2006). This procedure, like any ordinal measurement, provides no information about the intensity of the quality on which the samples are ordered or the size of the differences between them. Ranking is a simple approach to determining whether samples are judged as differing in intensity and entirely appropriate if only this information is required. But, as the number of samples increase, the cognitive demands also rise sharply. Thus, ordering three samples requires only 3 comparisons between these samples, but ordering 10 samples requires 45 such comparisons.

Interval measurement allows statements to be made about degree of difference between those things being measured.

Hence, both Fahrenheit and Celsius temperature scales are interval measures because the difference between 40 and 60 °C is equivalent to the difference between 70 and 90 °C. In sensory evaluation, the most commonly employed scales are considered to have this property. Scales that have equal categories are widely used to measure intensity (see Section Hedonic Ranking and Rating for the most commonly used hedonic category scale). There is no universal standard for number of categories, and 5-, 7-, 9-, 11-, 15-, and 21-point scales are seen. More categories ought, in theory, to provide better discrimination between samples. Some category scales use adjective labels (very strong, moderately strong, etc.), whereas others do not, but it is argued that labels assist the panelist to use the numbers in a consistent way. Sometimes, standards for parts of the scale are provided to insure consistency of use. Thus, in some descriptive analysis methods, trained panels will use 15-point scales (sometimes on which half-point ratings are also allowed), for which prior standards for some or all points/half-points have been established (see Section Descriptive Profiling/Analysis).

Despite the fact that interval scale labels are converted into scores – for example, from 1 (extremely weak) to 7 (extremely strong), the absence of valid zero point means that the data from these scales do not have ratio properties. Hence, one cannot conclude that a product that receives a rating of 6 (very strong) is twice as strong as one that receives a rating of 3 (moderately weak). The data from this type of scale are typically summarized using a mean and analyzed using analysis of variance (ANOVA) despite the fact that there is no guarantee that such data are normally distributed (e.g., Lim *et al.*, 2009).

Scales that remove categories and most of the labels have also been popular. The so-called line scale or visual analog scale (VAS) typically has anchor labels at either end (e.g., extremely weak/extremely strong) and sometimes a center anchor, often unlabeled. There is no consistency in the anchor labels used and to some extent they depend on the range of samples used. Otherwise, as a featureless line, it essentially provides for a much greater spread of ratings than does a category scale. Its proponents argue, therefore, that it offers greater discrimination among multiple samples. There is no evidence that the length of the line is important.

It is obviously of benefit to be able to make statements about the relative magnitude of sample qualities. To express relationships as ratios requires that the scale has a true zero that acts as a reference point for all other values and effectively means a zero amount of whatever is measured. Harvard psychologist Stevens (1956) developed a method known as magnitude estimation (ME) (ISO11056, 1999), which was based on the assumption that one's use of numbers itself exhibits ratio properties. Hence, when asked to name a number twice as great as 25, 50 is the only answer. If these properties are then transferred to sensory qualities and a true zero is used, then ratio measurement ought to be the result. So, as ME is implemented, panelists are asked to attach numbers to sensory qualities in proportion to their perceived magnitude. For example, if sample B is twice as sweet as sample A, the author gives a score for sample B that is twice the score given to sample A. It does not matter what number the author gives to sample A (except that negative numbers are not permitted) as long as all subsequent samples are given numbers that are proportional: half, twice, thrice, and so on. Despite the fact that ME appears intuitive to use, and was a popular method among researchers in the 1960s and 1970s, its use in sensory evaluation generally has been limited. This is almost certainly due to the fact that some period of instruction and practice is needed for its reliable use (Moskowitz, 1977).

A more recent solution to generating data with ratio properties has been the use of the labeled magnitude scale (LMS). This was developed by taste and smell researchers at least partly in response to the problem of ceiling effects in interval scaling (Green *et al.*, 1993). Thus, a series of high-intensity stimuli might all be rated as extremely strong on a category scale, despite intensity differences, so that the ratings are compressed against the 'ceiling' of the scale. With the LMS, the scale's labels are common intensity terms, such as barely detectable, weak, moderate, strong, and very strong, whose position on the scale was determined by ratings of the relative magnitude of the words themselves. The resultant scale provides labels that are quasi-logarithmically spaced. In addition to the label spacing, the top end of the scale also distinguishes the LMS from standard category scales by using the term strongest imaginable (**Figure 3(b)**). Originally, this referred just to the domain of all tastes (if tastants were being rated), but subsequent modifications (Bartoshuk *et al.*, 2004) of the scale have meant that strongest imaginable now more commonly refers to sensations of any kind ever experienced (this is referred to as the general labeled magnitude scale; gLMS).

Again, this scale is, as yet, more accepted by sensory researchers than by practitioners in industry because some training in the scale's use is required, particularly in relation to the meaning of strongest imaginable. Without practice, inexperienced panelists will often place the strongest of a set of samples at or near the top of the LMS, even though on the gLMS, this point is meant to be outside (and more intense than) the samples currently being evaluated.

Time-Intensity Scaling

It has been recognized for some time that not all of the sensory information that is crucial for understanding product perceptions can be captured by a rating of an attribute at a single point in time. The release of flavors from foods happens over time, as do the interactions between the odors, tastes, and tactile properties of the foods. In particular, events such as swallowing can change the balance of the sensory in-mouth experience, as can the effects of temperature in the mouth (e.g., chocolate melting) or chewing. Aftertastes, too, can be the crucial determinant of acceptability of a food. As a result, time-intensity (TI) measures have been employed to reflect changes in sensory attributes that occur once a food or beverage is in the mouth until the demise of the sensations, typically following swallowing (Cliff and Heymann, 1993). Typically, via either repeated discrete ratings of an attribute at set intervals (e.g., every 5 s) or continuous ratings using a computer-interfaced device, such as a mouse, TI information is used to generate a curve of intensity across time (often a few minutes) (**Figure 4**). Although there is no consensus on the question of which measures extracted from these TI curves best predict consumer preferences, common parameters include

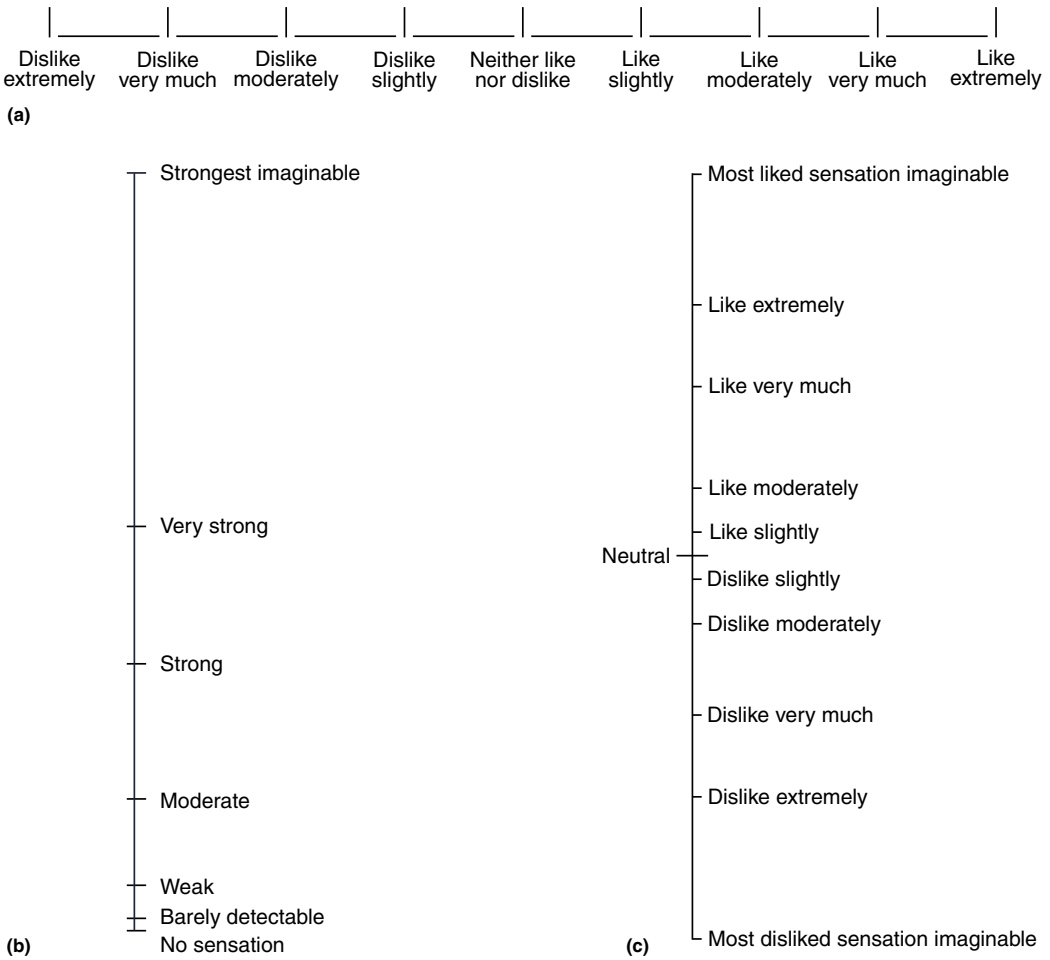

Figure 3 Intensity and hedonic scales. (a) The nine-point hedonic category scale. (b) The LMS. (c) The LHS.

maximum intensity, time to maximum intensity, total duration, rate of decline in intensity, and overall intensity (area under the curve). Also in use – but less widely than TI methods – are methods that directly assess the hedonic consequences of the time-course of sensory experience by measuring liking during the course of food consumption (Kremer *et al.*, 2013; Veldhuizen *et al.*, 2006).

Although providing valuable information, traditional TI methods are limited. The primary issue is that foods and beverages are inherently multisensory, whereas TI methods are typically useful for measuring only one of two attributes at a time. This means that a complete evaluation of a single complex product may take many sessions to complete. Moreover, TI methods do not provide any measure of the relative importance to the product experience of the attributes themselves.

In response to these drawbacks, several approaches have been used, including multiattribute TI (MATI) and temporal dominance of sensations (TDS) methods. In MATI, participants make ratings for multiple sensations repeatedly at discrete, fixed intervals, typically 15 or 30 s (e.g., Green and Hayes, 2003; Prescott and Stevenson, 1995). This approach

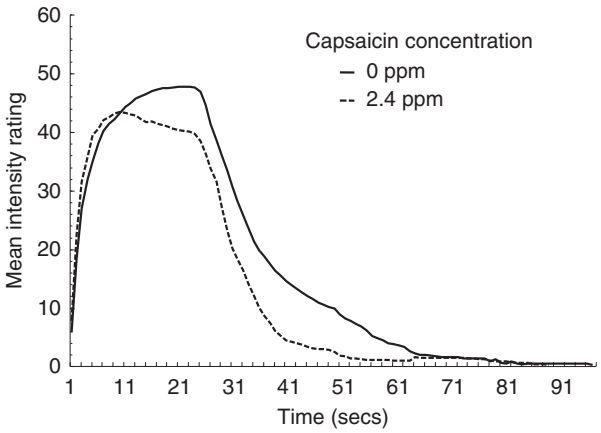

Figure 4 A tTI graph showing the impact of adding the pungent compound capsaicin to apple puree on ratings of apple flavor over time. Note that many of the effects are only evident at time periods that would not be captured by ratings made at a single time point. Of relevance also is the fact that these data were collected over two sessions, a limitation of traditional TI methods when compared with more recent techniques such as TDS (Prescott and Francis, 1997).

allows the sensory specialist to compare the relative intensity of different sensations with one another within a single test session. However, with a significant number of attributes, the temporal resolution may still be too coarse for the phenomenon of interest. Additionally, there is some evidence that participants may smear their ratings across multiple attributes (e.g., Bennett and Hayes, 2012). As an alternative, the TDS method was developed as a means of measuring the relative dominance (salience) of multiple sensory attributes over the duration of a single tasting/consumption session (Pineau *et al.*, 2009). The TDS method also allows for each sensation to be rated for intensity because it recognizes that an attribute may be dominant in other ways – for example, unusual, attention grabbing – rather than solely by its high relative intensity. The method presents all attributes (although a maximum of approximately 10 within each session is recognized) on a computer screen and the panelist is able to select, over the time-course of the sensation, which sensory attribute is dominant at that particular time point. Deciding that, overall, a particular attribute is dominant at a particular point (e.g., 5 s after swallowing) is based on calculating the proportion of times (taken over panelists and any replications) for which the given attribute was assessed as dominant at that point.

It has been recognized that TDS shares many similarities with conventional sensory profiling/descriptive analysis (see Section Descriptive Profiling/Analysis). Comparisons between the two methods have found that the methods tend to produce similar profiles, with those sensations that are dominant in TDS also being given high-intensity ratings in descriptive approaches (Dinnella *et al.*, 2012; Labbe *et al.*, 2009).

Descriptive Profiling/Analysis

Products can be defined in terms of a recipe of ingredients, but this is seldom adequate to reflect accurately the perceptions the product produces. Describing and measuring sensory attributes is a major activity within the food and other consumer goods industries as a way of understanding how product attributes influence preferences. The ultimate goal of such descriptive analysis is to generate quantitative profiles of a product or a series of products. Because instruments are not able to measure perceptions, this process involves using humans as sensors. Descriptive analysis may initially appear similar to focus group methods used in market research, but they are fundamentally different in that a large amount of effort is put into aligning and calibrating the language and the measurements that panelists use for consistency and precision. Also, once panelists undergo the calibration process, they are no longer considered representative of naive consumers, both because they use an analytic mindset and because they have been trained to attend to attributes of which naive consumers might be unaware. The dogma of the field holds that trained panelists should not be asked for affective or acceptability ratings (in contrast to the commodity-judging approaches mentioned in Section Issues of Good Sensory Practice). Accordingly, the phrase 'trained panels' is often used as shorthand to distinguish these individuals from other sensory methods. Finally, unlike focus groups that require the transcripts to be coded to identify qualitative themes, the data generated from descriptive profiling are inherently quantitative in nature.

Early approaches to profiling products quantitatively include the Flavor Profile® and the Texture Profile® developed, respectively, by Caul, Sjostrom, and Cairncross in the 1950s and by Szczesniak, Civille, and Liska in the 1960s. These approaches are not commonly used today, so they will not be discussed further. Interested, readers should see Lawless and Heymann (2010) and Moskowitz *et al.* (2003) for more information. By the end of the 1970s, two major methods had emerged to generate descriptive profiles: Spectrum Descriptive Analysis® and Quantitative Descriptive Analysis™. In spite of some key methodological and philosophical differences, these approaches are broadly similar in that both involve three key steps: (1) panelist training and lexicon development, (2) measurement of panelist reliability and calibration, and (3) evaluation of the test samples.

There is general agreement that a trained panel should consist of 8–12 motivated individuals who can be regularly and consistently available – panel training is typically intensive and can take months to achieve acceptable levels of performance (ISO13299, 2003). Some 'online' quality control panels use fewer members, but these panels are generally restricted to assessing a limited set of identical products (Munoz, 2002). The individuals are screened to exclude those with poor discriminative ability or lacking in verbal skills. This is commonly done using tests for ability to tell odor and taste qualities apart and to elicit a reasonable degree of descriptive ability for the qualities of the types of products being tested. Other exclusion criteria include ill health, especially if it affects the senses of taste and smell, smoking, and inadequate dentition. Age is not necessarily a key factor if other criteria are met (ISO8586, 2012).

Semantic error – assuming all participants attach the same meaning to the same word – can be a major source of variance if explicit steps are not taken to minimize it. For example, although most untrained consumers can probably rate 'sweetness' or 'bitterness,' they probably lack consensus on what is meant by 'creaminess' – it may be exclusively a textural attribute for some individuals, whereas for others, this term encompasses both mouthfeel and an olfactory dairy note. Accordingly, in both Spectrum and quantitative descriptive analysis (QDA), a large amount of emphasis is placed on concept formation and alignment among the participants during the initial training phase. This may be a top-down process, where the panel leader provides a list of descriptors, with definitions and physical references, as is done in the Spectrum method, or it may emerge from the group during the generation of a consensus, as occurs in the QDA method. Irrespective of which approach is used, the act of concept alignment is based on the psychological processes of abstraction and generalization, in which an individual learns to extract salient commonalities from a set of stimuli and then apply those abstractions to new stimuli.

In developing a lexicon, selecting appropriate terms (descriptors) is critical, as the panel leader must consider not only how the panelist perceives the product but also how they transmit this information. Lawless and Heymann (2010) identified criteria for selecting good descriptors: (1) they discriminate among products; (2) they are nonredundant

(i.e., little to no overlap); (3) they are simple, singular, and atomistic (i.e., not a combination of several other attributes); (4) there is consensus about their meaning; (5) they are unambiguous and easily recognizable in products; (6) they have communication value (i.e., not jargon and simply defined); (7) they relate to consumer acceptance/rejection; and (8) they relate to physical variables or instrumental measures. The use of physical references in the form of samples varying quantitatively and qualitatively is highly recommended, as they help a participant to decide what is or is not included within a concept. This is important when a concept has a poorly defined boundary. Also, use of reference stimuli helps to align concepts across panelists to ensure that they are using the same semantic label for the same underlying percept. For example, does the attribute lemon odor reflect the odor of lemonade, lemon juice, lemon peel, or artificial lemon flavoring?

A crucial aspect of all modern descriptive analysis techniques is training to achieve alignment between panelists of measurements of sensory qualities. In effect, this means that panelists learn to agree that a particular level of an attribute represents a particular value on the rating scale being used. So, even though all panelists may discriminate well between the samples/products being evaluated, at least initially they may use different parts of the scale in their ratings. To facilitate agreement between panelists on which parts of the scale to use, the panel trainer can provide reference samples to represent the scale extremes plus some intermediate points. However, there are also published references for scale values, especially in the evaluation of textural properties (e.g., Munoz, 1986).

The second step in descriptive profiling is to evaluate the reliability of the individual judges and the group as a whole (ISO11132, 2012). This is done by presenting actual products (not references) to panelists as if they are evaluating the final product. The sensory specialist can then analyze the data to see if all panelists are in agreement across multiple products. This process may identify problematic terms that require targeted retraining for the group as whole or it may identify a specific panelist who needs retraining to better align with the group. Traditionally, the sensory specialist would perform such analyses offline and debrief panelists at a later time. However, recent advances in computerized data collection and panelist training now allow the sensory specialist to provide immediate feedback to panelists (e.g., Findlay *et al.*, 2007). Use of instant feedback via software reportedly increases the salience of the feedback and decreases panel training time (Findlay *et al.*, 2006). Sophisticated statistical toolkits (e.g., *Panel Check*; *SensoMineR*) for measuring panel performance are also available as freeware.

The final step in descriptive profiling is to evaluate the product set of interest. Standard best practices – for example, blind presentation, appropriate portion sizes, counterbalanced presentation order, etc. – should be used (see Section Issues of Good Sensory Practice). Products are typically tested in at least triplicate to ensure a sufficient number of data points per attribute per product (i.e., 12 panelists × 3 replicates = 36 observations). Data are then analyzed via ANOVA to account for remaining panelist variability, and significant differences across products within attributes are tabulated or summarized graphically.

Descriptive analyses can produce product profiles consisting of tens of different sensory attributes. There is no guarantee either that all of these attributes are independent from one another or that they are equally important in discriminating the products. A common way of dealing with these issues is by determining the underlying dimensions of the sensory data using a technique such as principal components analysis (PCA; a type of factor analysis). The PCA summarizes the dataset by extracting a smaller number of independent dimensions (ideally, 2 or 3 that explain a high proportion of the variance in the data) than the number of attributes that are being measured. These dimensions (principal components; PCs) are linear combinations of correlated attributes. For example, measuring a set of attributes for desserts might produce a PC that is a combination of the ratings of vanilla odor, viscosity, and mouth coating. The PCA then correlates the original set of attributes with the dimensions as a way of describing what the dimension represents. So, each of these attributes will have high factor loading on PC1 (the component that explains the highest proportion of the data variance), a reasonable interpretation of which is that it represents creaminess.

Affective Consumer Methods

Ultimately, irrespective of the product, the aim of sensory science in an industrial context is most often to insure that consumer preferences are met. Although to some extent consumer sensory evaluation techniques emerged from those methods used to judge commodities such as wines and cheeses, they differ from these in that it is implicit within sensory evaluation that the best product is whatever the consumer says it is, rather than what an expert says is best. Although consumer evaluations are thought to measure liking, it is important to be aware that even though terms such as acceptability and preference are often used synonymously with liking, there can be subtle but important differences. For instance, are Brussels sprouts preferred to spinach? It may be easy enough to respond to this question, but the answer does not tell one the extent to which either vegetable is actually liked. Similarly, an individual may say that beer is a 'liked' beverage overall, but they only find it acceptable within specified contexts (e.g., not at 8 a.m.). As with any tool, appropriate usage is determined by the question being asked.

Interpretation of consumer data also requires an understanding of the nature of consumers' responses, how these are shaped by the test being administered, and what constraints are inherent in the method. It is a truism that consumer responses are subjective in nature. Scientists used to making measurements instrumentally rather than behaviorally often find this troubling. Specifically, 'subjectivity' becomes equated with variability, unreliability, and lack of veracity (see Section Individual Differences).

The practical way of dealing with variability in consumer data is to make sure that the test being used has sufficient power to detect differences between products. Although power is partly a function of the test itself and the size of any differences between products, sufficient power in consumer tests is typically established by using an appropriately large sample

of consumers. Certainly, if very large numbers of consumers are required to show differences between products, then the products are more likely to be equally liked for all practical purposes. A figure of 100 consumers is sometimes given as a realistic minimum. Although no single figure has universal validity, an analysis of the standard error of a set of similar studies, using conventional Type-I and -II error rates, gave an estimation of a sample size of 112 (Hough *et al.*, 2006). However, any subdivision of a sample of this size in terms of age, sex, etc. will rapidly diminish the power of the evaluation to show product differences (see Section How Many Participants?).

The variability of consumer data is often cited as one reason why consumers should not be used to generate product ratings of the sensory characteristics of products, as trained panels do (see Section Descriptive Profiling/Analysis). This problem can be exacerbated by potentially additional variability arising variations in understanding the meaning of sensory characteristics. Although it probably requires no training for consumers to be consistent about the meaning of sweetness or saltiness, the majority of sensory characteristics – and especially those related to texture – involve the learning of specific definitions of terms and concept alignment among participants. For example, an attribute such as 'creamy' has both a textural and an olfactory component, and consumers may differentially attend to each of these aspects when asked to rate 'creaminess.'

One way of looking at consumer perceptions is that they are both hedonic and global. Like one's own responses to food at mealtimes, consumer responses are typically not highly analytical, but rather a response to the whole flavor and the pleasure that it evokes. This is, of course, in contrast to how trained panelists in descriptive analysis respond, because their training involves a reliance on being analytical as well as treating the product as a collection of attributes, rather than as a whole flavor or food. Recently, it has been demonstrated that these contrasting styles of responding to products have measurable consequences. Inducing an analytical frame of mind in consumers during a product evaluation by simply listing a set of sensory attributes to be rated reduced the magnitude of an overall liking rating that was completed first (Prescott *et al.*, 2011).
